IMPORTANT NOTICE

Texas Instruments and its subsidiaries (TI) reserve the right to make changes to their products or to discontinue any product or service without notice, and advise customers to obtain the latest version of relevant information to verify, before placing orders, that information being relied on is current and complete. All products are sold subject to the terms and conditions of sale supplied at the time of order acknowledgment, including those pertaining to warranty, patent infringement, and limitation of liability.

TI warrants performance of its products to the specifications applicable at the time of sale in accordance with TI’s standard warranty. Testing and other quality control techniques are utilized to the extent TI deems necessary to support this warranty. Specific testing of all parameters of each device is not necessarily performed, except those mandated by government requirements.

Customers are responsible for their applications using TI components.

In order to minimize risks associated with the customer’s applications, adequate design and operating safeguards must be provided by the customer to minimize inherent or procedural hazards.

TI assumes no liability for applications assistance or customer product design. TI does not warrant or represent that any license, either express or implied, is granted under any patent right, copyright, mask work right, or other intellectual property right of TI covering or relating to any combination, machine, or process in which such products or services might be or are used. TI’s publication of information regarding any third party’s products or services does not constitute TI’s approval, license, warranty or endorsement thereof.

Reproduction of information in TI data books or data sheets is permissible only if reproduction is without alteration and is accompanied by all associated warranties, conditions, limitations and notices. Representation or reproduction of this information with alteration voids all warranties provided for an associated TI product or service, is an unfair and deceptive business practice, and TI is not responsible nor liable for any such use.

Resale of TI’s products or services with statements different from or beyond the parameters stated by TI for that products or service voids all express and any implied warranties for the associated TI product or service, is an unfair and deceptive business practice, and TI is not responsible nor liable for any such use.

About This Manual

DSP/BIOS gives developers of mainstream applications on Texas Instruments TMS320 DSP devices the ability to develop embedded real-time software. DSP/BIOS provides a small firmware real-time library and easy-to-use tools for real-time tracing and analysis.

You should read and become familiar with the TMS320 DSP/BIOS API Reference Guide for your platform. The API reference guide is a companion volume to this user's guide.

Before you read this manual, you should follow the tutorials: TMS320 "Using DSP/BIOS" lessons in the online Code Composer Studio Tutorial and DSP/BIOS section of the online help system to get an overview of DSP/BIOS. This manual discusses various aspects of DSP/BIOS in depth and assumes that you have at least a basic understanding of other aspects of DSP/BIOS as found in the help systems.

Notational Conventions

This document uses the following conventions:

- Program listings, program examples, and interactive displays are shown in a special typeface. Examples use a bold version of the special typeface for emphasis; interactive displays use a bold version of the special typeface to distinguish commands that you enter from items that the system displays (such as prompts, command output, error messages, etc.).

Here is a sample program listing:

```c
Void copy(HST_Obj *input, HST_Obj *output)
{
    PIP_Obj     *in, *out;
    Uns         *src, *dst;
    Uns         size;
}
```
Solution:

Square brackets ([ and ]) identify an optional parameter. If you use an optional parameter, you specify the information within the brackets. Unless the square brackets are in a **bold** typeface, do not enter the brackets themselves.

Throughout this manual, 54 can represent the two-digit numeric appropriate to your specific DSP platform. If your DSP platform is C62x based, substitute 62 each time you see the designation 54. For example, DSP/BIOS assembly language API header files for the C6000 platform will have a suffix of .h62. For a C64x or C55x DSP platform, substitute either 64 or 55 for each occurrence of 54. Also, each reference to Code Composer Studio C5000 can be substituted with Code Composer Studio C6000 depending on your DSP platform.

Information specific to a particular device is designated with one of the following icons:

![Device Icons]

**Related Documentation From Texas Instruments**

The following books describe TMS320 devices and related support tools. To obtain a copy of any of these TI documents, call the Texas Instruments Literature Response Center at (800) 477-8924. When ordering, please identify the book by its title and literature number.

**TMS320C6000 DSP/BIOS Application Programming Interface (API) Reference Guide** (literature number SPRU403) describes the DSP/BIOS API functions, which are alphabetized by name. In addition, there are reference sections that describe the overall capabilities of each module, and appendices that provide tables that are useful to developers. The API Reference Guide is the companion to this user’s guide.

**TMS320C5000 DSP/BIOS Application Programming Interface (API) Reference Guide** (literature number SPRU404) describes the DSP/BIOS API functions, which are alphabetized by name. In addition, there are reference sections that describe the overall capabilities of each module, and appendices that provide tables that are useful to developers. The API Reference Guide is the companion to this user’s guide.
TMS320C54x Assembly Language Tools User’s Guide (literature number SPRU102) describes the assembly language tools (assembler, linker, and other tools used to develop assembly language code), assembler directives, macros, common object file format, and symbolic debugging directives for the C5000 generation of devices.

TMS320C55x Assembly Language Tools User’s Guide (literature number SPRU280) describes the assembly language tools (assembler, linker, and other tools used to develop assembly language code), assembler directives, macros, common object file format, and symbolic debugging directives for the C5000 generation of devices.

TMS320C6000 Assembly Language Tools User’s Guide (literature number SPRU186) describes the assembly language tools (assembler, linker, and other tools used to develop assembly language code), assembler directives, macros, common object file format, and symbolic debugging directives for the C5000 generation of devices.

TMS320C54x Optimizing C Compiler User’s Guide (literature number SPRU103) describes the C54x C compiler. This C compiler accepts ANSI standard C source code and produces TMS320 assembly language source code for the C54x generation of devices.

TMS320C55x Optimizing C Compiler User’s Guide (literature number SPRU281) describes the C55x C compiler. This C compiler accepts ANSI standard C source code and produces TMS320 assembly language source code for the C55x generation of devices.

TMS320C6000 Optimizing C Compiler User’s Guide (literature number SPRU187) describes the C6000 C/C++ compiler and the assembly optimizer. This C/C++ compiler accepts ANSI standard C/C++ source code and produces assembly language source code for the C6000 generation of devices. The assembly optimizer helps you optimize your assembly code.

TMS320C55x Programmer’s Guide (literature number SPRU376) describes ways to optimize C and assembly code for the TMS320C55x DSPs and includes application program examples.

TMS320C6000 Programmer’s Guide (literature number SPRU189) describes the C6000 CPU architecture, instruction set, pipeline, and interrupts for these digital signal processors.
Related Documentation From Texas Instruments

**TMS320C54x DSP Reference Set, Volume 1: CPU and Peripherals** (literature number SPRU131) describes the TMS320C54x 16-bit fixed-point general-purpose digital signal processors. Covered are its architecture, internal register structure, data and program addressing, the instruction pipeline, and on-chip peripherals. Also includes development support information, parts lists, and design considerations for using the XDS510 emulator.

**TMS320C54x DSP Enhanced Peripherals Ref Set, Vol 5** (literature number SPRU302) describes the enhanced peripherals available on the TMS320C54x digital signal processors. Includes the multi channel buffered serial ports (McBSPs), direct memory access (DMA) controller, interprocessor communications, and the HPI-8 and HPI-16 host port interfaces.

**TMS320C54x DSP Mnemonic Instruction Set Reference Set Volume 2** (literature number SPRU172) describes the TMS320C54x digital signal processor mnemonic instructions individually. Also includes a summary of instruction set classes and cycles.

**TMS320C54x DSP Reference Set, Volume 3: Algebraic Instruction Set** (literature number SPRU179) describes the TMS320C54x digital signal processor algebraic instructions individually. Also includes a summary of instruction set classes and cycles.

**TMS320C6000 Peripherals Reference Guide** (literature number SPRU190) describes common peripherals available on the TMS320C6000 family of digital signal processors. This book includes information on the internal data and program memories, the external memory interface (EMIF), the host port, multichannel buffered serial ports, direct memory access (DMA), clocking and phase-locked loop (PLL), and the power-down modes.

**TMS320C54x Code Composer Studio Tutorial Online Help** (literature number SPRH134) introduces the Code Composer Studio integrated development environment and software tools. Of special interest to DSP/BIOS users are the Using DSP/BIOS lessons.

**TMS320C55x Code Composer Studio Tutorial Online Help** (literature number SPRH097) introduces the Code Composer Studio integrated development environment and software tools. Of special interest to DSP/BIOS users are the Using DSP/BIOS lessons.

**TMS320C6000 Code Composer Studio Tutorial Online Help** (literature number SPRH125) introduces the Code Composer Studio integrated development environment and software tools. Of special interest to DSP/BIOS users are the Using DSP/BIOS lessons.
Related Documentation

**Code Composer Studio Application Program Interface (API) Reference Guide** (literature number SPRU321) describes the Code Composer Studio application programming interface, which allows you to program custom analysis tools for Code Composer Studio.

**DSP/BIOS and TMS320C54x Extended Addressing** (literature number SPRA599) provides basic run-time services including real-time analysis functions for instrumenting an application, clock and periodic functions, I/O modules, and a preemptive scheduler. It also describes the far model for extended addressing, which is available on the TMS320C54x platform.

**TMS320C6000 Chip Support Library API Reference Guide** (literature number SPRU401) contains a reference for the Chip Support Library (CSL) application programming interfaces (APIs). The CSL is a set of APIs used to configure and control all on-chip peripherals.

**Related Documentation**

Contents

1 About DSP/BIOS ......................................................... 1-1
DSP/BIOS is a scalable real-time kernel. It is designed for applications that require real-time scheduling and synchronization, host-to-target communication, or real-time instrumentation. DSP/BIOS provides preemptive multi-threading, hardware abstraction, real-time analysis, and configuration tools.
  1.1 DSP/BIOS Features and Benefits .................................. 1-2
  1.2 DSP/BIOS Components ............................................ 1-4
  1.3 Naming Conventions ............................................. 1-11
  1.4 For More Information ........................................... 1-17

2 Program Generation .................................................... 2-1
This chapter describes the process of generating programs with DSP/BIOS. It also explains which files are generated by DSP/BIOS components and how they are used.
  2.1 Development Cycle ............................................... 2-2
  2.2 Using the Configuration Tool .................................... 2-3
  2.3 Files Used to Create DSP/BIOS Programs ....................... 2-12
  2.4 Compiling and Linking Programs ............................... 2-14
  2.5 Using DSP/BIOS with the Run-Time Support Library .......... 2-18
  2.6 DSP/BIOS Startup Sequence .................................... 2-20
  2.7 Using C++ with DSP/BIOS ....................................... 2-24
  2.8 User Functions Called by DSP/BIOS ........................... 2-27
  2.9 Calling DSP/BIOS APIs from Main .............................. 2-28

3 Instrumentation .......................................................... 3-1
DSP/BIOS provides both explicit and implicit ways to perform real-time program analysis. These mechanisms are designed to have minimal impact on the application’s real-time performance.
  3.1 Real-Time Analysis ............................................... 3-2
  3.2 Instrumentation Performance .................................... 3-3
  3.3 Instrumentation APIs ............................................. 3-6
  3.4 Implicit DSP/BIOS Instrumentation ............................. 3-18
  3.5 Kernel/Object View Debugger ................................. 3-28
  3.6 Instrumentation for Field Testing .............................. 3-37
  3.7 Real-Time Data Exchange ....................................... 3-37
### 4 Thread Scheduling

This chapter describes the types of threads a DSP/BIOS program can use, their behavior, and their priorities during program execution.

- **4.1 Overview of Thread Scheduling**
- **4.2 Hardware Interrupts**
- **4.3 Software Interrupts**
- **4.4 Tasks**
- **4.5 The Idle Loop**
- **4.6 Semaphores**
- **4.7 Mailboxes**
- **4.8 Timers, Interrupts, and the System Clock**
- **4.9 Periodic Function Manager (PRD) and the System Clock**
- **4.10 Using the Execution Graph to View Program Execution**

### 5 Memory and Low-level Functions

This chapter describes the low-level functions found in the DSP/BIOS real-time multitasking kernel. These functions are embodied in three software modules: MEM, which manages allocation of memory; SYS, which provides miscellaneous system services; and QUE, which manages queues.

- **5.1 Memory Management**
- **5.2 System Services**
- **5.3 Queues**

### 6 Input/Output Overview and Pipes

This chapter provides an overview on data transfer methods, and discusses pipes in particular.

- **6.1 I/O Overview**
- **6.2 Comparing Pipes and Streams**
- **6.3 Data Pipe Manager (PIP Module)**
- **6.4 Host Channel Manager (HST Module)**
- **6.5 I/O Performance Issues**

### 7 Streaming I/O and Device Drivers

This chapter describes issues relating to writing and using device drivers, and gives several programming examples.

- **7.1 Overview of Streaming I/O and Device Drivers**
- **7.2 Creating and Deleting Streams**
- **7.3 Stream I/O—Reading and Writing Streams**
- **7.4 Stackable Devices**
- **7.5 Controlling Streams**
- **7.6 Selecting Among Multiple Streams**
- **7.7 Streaming Data to Multiple Clients**
- **7.8 Streaming Data Between Target and Host**
- **7.9 Device Driver Template**
- **7.10 Streaming DEV Structures**
- **7.11 Device Driver Initialization**
- **7.12 Opening Devices**

1.1 DSP/BIOS Features and Benefits

DSP/BIOS and its Analysis Tool for Code Composer Studio software are designed to minimize memory and CPU requirements on the target. This design goal is accomplished in the following ways:

- All DSP/BIOS objects can be created in the Configuration Tool and bound into an executable program image. This reduces code size and optimizes internal data structures.
- Instrumentation data (such as logs and traces) are formatted on the host.
- The APIs are modularized so that only those APIs that are used by the program need to be bound into the executable program.
- The library is optimized to require the smallest possible number of instruction cycles, with a significant portion implemented in assembly language.
- Communication between the target and the DSP/BIOS Analysis Tools is performed within the background idle loop. This ensures that the DSP/BIOS Analysis Tools do not interfere with the program's tasks. If the target CPU is too busy to perform background tasks, the DSP/BIOS Analysis Tools stop receiving information from the target until the CPU is available.

In addition, the DSP/BIOS API provides many options for program development:

- A program can dynamically create and delete objects that are used in special situations. The same program can use both objects created dynamically and objects created with the Configuration Tool.
- The threading model provides thread types for a variety of situations. Hardware interrupts, software interrupts, tasks, idle functions, and periodic functions are all supported. You can control the priorities and blocking characteristics of threads through your choice of thread types.
- Structures to support communication and synchronization between threads are provided. These include semaphores, mailboxes, and resource locks.
- Two I/O models are supported for maximum flexibility and power. Pipes are used for target/host communication and to support simple cases in which one thread writes to the pipe and another reads from the pipe. Streams are used for more complex I/O and to support device drivers.
- Low-level system primitives are provided to make it easier to handle errors, create common data structures, and manage memory usage.
- The Chip Support Library (CSL) is a component of DSP/BIOS and can be used within a DSP/BIOS application.
The DSP/BIOS API standardizes DSP programming for a number of TI devices and provides easy-to-use powerful program development tools. These tools reduce the time required to create DSP programs in the following ways:

- The Configuration Tool generates code required to declare objects used within the program.
- The Configuration Tool detects errors earlier by validation properties before the program is even built.
- Logging and statistics for DSP/BIOS objects are available at run-time without additional programming. Additional instrumentation can be programmed as needed.
- The DSP/BIOS Analysis Tools allow real-time monitoring of program behavior.
- DSP/BIOS provides a standard API. This allows DSP algorithm developers to provide code that can be more easily integrated with other program functions.
- DSP/BIOS is integrated within the Code Composer Studio IDE, requires no runtime license fees, and is fully supported by Texas Instruments. DSP/BIOS is a key component of TI’s eXpressDSP™ real-time software technology.
- The Chip Support Library (CSL) provides an easier method of device programming than traditional register programming. When you use CSL APIs, portability between different DSP platforms with equivalent peripheral devices is simpler and more efficient.
1.2 DSP/BIOS Components

Figure 1-1 shows the components of DSP/BIOS within the program generation and debugging environment of Code Composer Studio:

On the host PC, you write programs (in C, C++ or assembly) that use the DSP/BIOS API. The Configuration Tool lets you define objects to be used in your program. You then compile or assemble and link the program. The DSP/BIOS Analysis Tools let you test the program on the target device from Code Composer Studio while monitoring CPU load, timing, logs, thread execution, and more. (The term thread is used to refer to any thread of execution, i.e., a hardware interrupt, a software interrupt, a task, an idle function, or a periodic function.)

The following sections provide a brief overview of the DSP/BIOS components.
1.2.1 DSP/BIOS Real-Time Kernel and API

DSP/BIOS is a scalable real-time kernel, designed for applications that require real-time scheduling and synchronization, host-to-target communication, or real-time instrumentation. DSP/BIOS provides preemptive multi-threading, hardware abstraction, real-time analysis, and configuration tools.

The DSP/BIOS API is divided into modules, however, the CSL is actually a sub-component of BIOS, with many sub-modules of its own. For simplicity, references to the CSL in this manual use the term, CSL module. Depending on what modules are configured and used by the application, the size of DSP/BIOS can range from about 500 to 6500 words of code. All the operations within a module begin with the letter codes shown Figure 1-1. For more information on the CSL, see *TMS320C6000 Chip Support Library API Reference Guide*, literature number SPRU401.

Application programs use DSP/BIOS by making calls to the API. All DSP/BIOS modules provide C-callable interfaces. In addition, some of the API modules contain optimized assembly language macros. Most C-callable interfaces can also be called from assembly language, provided that C calling conventions are followed. Some of the C interfaces are actually C macros and therefore, cannot be used when called from assembly language. Refer to the *TMS320 DSP/BIOS API Reference Guide* for your platform for descriptions of the applicable C and assembly languages interfaces for all DSP/BIOS modules.

1.2.2 The DSP/BIOS Configuration Tool

The Configuration Tool has an interface similar to the Windows Explorer, and has multiple roles:

- It lets you set a wide range of parameters used by the DSP/BIOS real-time library at run time.
It serves as a visual editor for creating run-time objects that are used by the target application’s DSP/BIOS API calls. These objects include software interrupts, tasks, I/O streams, and event logs. You also use this visual editor as shown in Figure 1-2 to set properties for these objects.

It lets you set parameters for the Chip Support Library (CSL) and modules. See the *TMS320C6000 Chip Support Library*, SPRU401 for more information.

**Figure 1-2. Configuration Tool Interface**
Using the Configuration Tool, DSP/BIOS objects can be pre-configured and bound into an executable program image. Alternately, a DSP/BIOS program can create and delete objects at run time. In addition to minimizing the target memory footprint by eliminating run-time code and optimizing internal data structures, creating static objects with the Configuration Tool detects errors earlier by validating object properties before program compilation.

The Configuration Tool generates files that link with code you write. See section 2.2, *Using the Configuration Tool*, page 2-3, for details.

### 1.2.3 The DSP/BIOS Analysis Tools

The DSP/BIOS Analysis Tools complement the Code Composer Studio environment by enabling real-time program analysis of a DSP/BIOS application. You can visually monitor a DSP application as it runs with minimal impact on the application’s real-time performance. The DSP/BIOS Analysis Tools are found on their own menu, as shown in Figure 1-3.

#### Figure 1-3. The DSP/BIOS Menu

![DSP/BIOS Analysis Tools Menu]

Unlike traditional debugging, which is external to the executing program, program analysis requires the target program contain real-time instrumentation services. By using DSP/BIOS APIs and objects, developers automatically instrument the target for capturing and uploading real-time information to the host through the Code Composer Studio DSP/BIOS Analysis Tools.

Several broad real-time program analysis capabilities are provided:

- **Program tracing.** Displaying events written to target logs, reflecting dynamic control flow during program execution
- **Performance monitoring.** Tracking summary statistics that reflect use of target resources, such as processor load and timing
- **File streaming.** Binding target-resident I/O objects to host files
When used in tandem with the other debugging capabilities of Code Composer Studio, the DSP/BIOS real-time Analysis Tools provide critical views into target program behavior during program execution—where traditional debugging techniques that stop the target offer little insight. Even after the debugger halts the program, information already captured by the host with the DSP/BIOS Analysis Tools can provide insight into the sequence of events that led up to the current point of execution.

Later in the software development cycle, when regular debugging techniques become ineffective for attacking problems arising from time-dependent interactions, the DSP/BIOS Analysis Tools have an expanded role as the software counterpart of the hardware logic analyzer.

Figure 1-4 illustrates several of the DSP/BIOS Analysis Tools panels.

Figure 1-4. Code Composer Studio Analysis Tool Panels
Figure 1-5 shows the DSP/BIOS Analysis Tools toolbar, which can be toggled on and off by choosing View → Plug-in Toolbars → DSP/BIOS.

Figure 1-5. DSP/BIOS Analysis Tools Toolbar
1.3 Naming Conventions

Each DSP/BIOS module has a unique name that is used as a prefix for operations (functions), header files, and objects for the module. This name is comprised of 3 or more uppercase alphanumerics.

Throughout this manual, 54 represents the two-digit numeric appropriate to your specific DSP platform. If your DSP platform is C6200 based, substitute 62 each time you see the designation 54. For example, DSP/BIOS assembly language API header files for the C6000 platform will have a suffix of .h62. For a C5000 DSP platform, substitute either 54 or 55 for each occurrence of 54. Also, each reference to Code Composer Studio C5000 can be substituted with Code Composer Studio C6000.

All identifiers beginning with upper-case letters followed by an underscore (XXX_*) should be treated as reserved words.

1.3.1 Module Header Names

Each DSP/BIOS module has two header files containing declarations of all constants, types, and functions made available through that module’s interface.

- **xxx.h**: DSP/BIOS API header files for C programs. Your C source files should include std.h and the header files for any modules the C functions use.

- **xxx.h54**: DSP/BIOS API header files for assembly programs. Assembly source files should include the xxx.h54 header file for any module the assembly source uses. This file contains macro definitions specific to this device.

Your program must include the corresponding header for each module used in a particular program source file. In addition, C source files must include std.h before any module header files. (See section 1.3.4, Data Type Names, page 1-13, for more information.) The std.h file contains definitions for standard types and constants. After including std.h, you can include the other header files in any sequence. For example:

```
#include <std.h>
#include <tsk.h>
#include <sem.h>
#include <prd.h>
#include <swi.h>
```
DSP/BIOS includes a number of modules that are used internally. These modules are undocumented and subject to change at any time. Header files for these internal modules are distributed as part of DSP/BIOS and must be present on your system when compiling and linking DSP/BIOS programs.

1.3.2 Object Names

System objects that are included in the configuration by default typically have names beginning with a 3- or 4-letter code for the module that defines or uses the object. For example, the default configuration includes a LOG object called LOG_system.

**Note:**

Objects you create with the Configuration Tool should use a common naming convention of your choosing. You might want to use the module name as a suffix in object names. For example, a TSK object that encodes data might be called encoderTsk.

1.3.3 Operation Names

The format for a DSP/BIOS API operation name is MOD_action where MOD is the letter code for the module that contains the operation, and action is the action performed by the operation. For example, the SWI_post function is defined by the SWI module; it posts a software interrupt.

This implementation of the DSP/BIOS API also includes several built-in functions that are run by various built-in objects. Here are some examples:

- **CLK_F_isr.** Run by an HWI object to provide the low-resolution CLK tick.
- **PRD_F_tick.** Run by the PRD_clock CLK object to manage PRD_SWI and system tick.
- **PRD_F_swi.** Triggered by PRD_tick to run the PRD functions.
- **_KNL_run.** Run by the lowest priority SWI object, KNL_swi, to run the task scheduler if it is enabled. This is a C function called KNL_run. An underscore is used as a prefix because the function is called from assembly code.
- **_IDL_loop.** Run by the lowest priority TSK object, TSK_idle, to run the IDL functions.
- **IDL_F_busy.** Run by the IDL_cpuLoad IDL object to compute the current CPU load.
Naming Conventions

- **RTA_F_dispatch.** Run by the RTA_dispatcher IDL object to gather real-time analysis data.
- **LNK_F_dataPump.** Run by the LNK_dataPump IDL object to manage the transfer of real-time analysis and HST channel data to the host.
- **HWI_unused.** Not actually a function name. This string is used in the Configuration Tool to mark unused HWI objects.

**Note:**
Your program code should not call any built-in functions whose names begin with MOD_F_. These functions are intended to be called only as function parameters specified within the Configuration Tool.

Symbol names beginning with MOD_ and MOD_F_ (where MOD is any letter code for a DSP/BIOS module) are reserved for internal use.

1.3.4 Data Type Names

The DSP/BIOS API does not explicitly use the fundamental types of C such as int or char. Instead, to ensure portability to other processors that support the DSP/BIOS API, DSP/BIOS defines its own standard data types. In most cases, the standard DSP/BIOS types are uppercase versions of the corresponding C types.

The data types, shown in Table 1-2, are defined in the std.h header file.

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Arg</td>
<td>Type capable of holding both Ptr and Int arguments</td>
</tr>
<tr>
<td>Bool</td>
<td>Boolean value</td>
</tr>
<tr>
<td>Char</td>
<td>Character value</td>
</tr>
<tr>
<td>Int</td>
<td>Signed integer value</td>
</tr>
<tr>
<td>LgInt</td>
<td>Large signed integer value</td>
</tr>
<tr>
<td>LgUns</td>
<td>Large unsigned integer value</td>
</tr>
<tr>
<td>Ptr</td>
<td>Generic pointer value</td>
</tr>
<tr>
<td>String</td>
<td>Zero-terminated (\0) sequence (array) of characters</td>
</tr>
<tr>
<td>Uns</td>
<td>Unsigned integer value</td>
</tr>
<tr>
<td>Void</td>
<td>Empty type</td>
</tr>
</tbody>
</table>
Additional data types are defined in std.h, but are not used by the DSP/BIOS API.

In addition, the standard constant NULL (0) is used by DSP/BIOS to signify an empty pointer value. The constants TRUE (1) and FALSE (0) are used for values of type Bool.

Object structures used by the DSP/BIOS API modules use a naming convention of MOD_Obj, where MOD is the letter code for the object's module. If your program code uses any such objects created by the Configuration Tool, it should make an extern declaration for the object. For example:

```c
extern LOG_Obj trace;
```

The Configuration Tool automatically generates a C header to file that contains the appropriate declarations for all DSP/BIOS objects created by the Configuration Tool (<program>.cfg.h. This file can be included by the application's source files to accomplish the DSP/BIOS object declarations.

DSP/BIOS for the C54x platform was originally developed for the 16-bit addressing model of the early C54x devices. Newer C54x devices incorporate far extended addressing modes, and DSP/BIOS has been modified to work in this environment. See the Application Report, DSP/BIOS and TMS320C54x Extended Addressing, SPRA599, for more information.

### 1.3.5 Memory Segment Names

The memory segment names used by DSP/BIOS are described in Table 1-3.

#### Table 1-3. Memory Segment Names

**a. C54x Platform**

<table>
<thead>
<tr>
<th>Segment</th>
<th>Description</th>
</tr>

<td>IDRAM</td>
</tr>
</tbody>
</table>

You can change these default allocations by using the MEM Manager in the Configuration Tool. For more detail, see MEM Module in the TMS320 DSP/BIOS API Reference Guide for your platform.

1.4 For More Information

For more information about the components of DSP/BIOS and the modules in the DSP/BIOS API, see the DSP/BIOS section of the online help system, the TMS320 DSP/BIOS API Reference Guide for your platform, or the "Using DSP/BIOS" lessons in the online Code Composer Studio Tutorial.
This chapter describes the process of generating programs with DSP/BIOS. It also explains which files are generated by DSP/BIOS components and how they are used.

2.1 Development Cycle

DSP/BIOS supports iterative program development cycles. You can create the basic framework for an application and test it with a simulated processing load before the DSP algorithms are in place. You can easily change the priorities and types of program threads that perform various functions.

A sample DSP/BIOS development cycle includes the following steps, though iteration can occur for any step or group of steps:

1) Use the Configuration Tool to create objects for your program to use.

2) Save the configuration file, which generates files to be included when you compile and link your program.

3) Write a framework for your program. You can use C, C++, assembly, or a combination of the languages.

4) Compile and link the program using a Code Composer Studio makefile or a project.

5) Test program behavior using a simulator or initial hardware and the DSP/BIOS Analysis Tools. You can monitor logs and traces, statistics objects, timing, software interrupts, and more.

6) Repeat steps 1-5 until the program runs correctly. You can add functionality and make changes to the basic program structure.

7) When production hardware is ready, modify the configuration file to support the production board and test your program on the board.
2.2 Using the Configuration Tool

The Configuration Tool is a visual editor with an interface similar to the Windows Explorer. It allows you to initialize data structures and set various parameters used by DSP/BIOS. When you save a file, the Configuration Tool creates assembly source and header files and a linker command file to match your settings. When you build your application, these files are linked with your application programs. See the Configuration Tool lessons in the DSP/BIOS section of the online help system for more details on using the Configuration Tool.

2.2.1 Creating a New Configuration File

1) In the Code Composer Studio program, open the Configuration Tool by choosing File→New→DSP/BIOS Config. Alternatively, you can open the Configuration Tool outside of the Code Composer Studio program from the Start menu.

2) Choose the appropriate template and click OK.

2.2.2 Creating a Custom Template

You can add a custom template or seed file by creating a configuration file and storing it in your include folder. This saves time by allowing you to define configuration settings for your hardware once. Then you can reuse the file as a template.

For example, to build DSP/BIOS programs for a fixed or floating point DSP, you can use the settings provided. Or you can instruct the Configuration Tool to create a new custom template file for projects that should take advantage of the appropriate run-time library.

To create a custom template, for example, to change the DSP MIPS on the C54x platform, perform the following steps. Modify the steps as appropriate for other DSP/BIOS platforms.

1) Invoke the Configuration Tool from outside the Code Composer Studio software via Start→Programs→Code Composer Studio C5000→Configuration Tool.

2) From the File menu, choose New.

3) In the New window choose c54xx.cdb and click OK.

4) Right-click on Global Settings and choose Properties.

5) Set DSP MIPS (CLKOUT) to 200 and click OK.

6) Choose File→Save As. In the Save As dialog box navigate to ti\c5400\bios\include.

7) In the File Name box type c54x_200.cdb.
Using the Configuration Tool

8) In the Save as type box choose Seed files (*.cdb) and click Save.
9) In the Set Description dialog type a description and click OK.
10) In the Configuration Tool, choose File→Exit.

2.2.3 Setting Global Properties for a Module

1) When you choose a module (by clicking on it), the right side of the window shows the current properties for the module. (If you see a list of priorities instead of a property list, right-click on the module and choose Property/value view. If the right side of the window is gray, this module has no global properties.)

For help about a module, click ? and then click on the module.

2) Right-click the icon next to the module and choose Properties from the pop-up menu. This opens the property dialog.

3) Change properties as needed. For help on the module’s properties, click Help in the property dialog.

2.2.4 Creating Objects Using the Configuration Tool

Most objects can be created either statically using the Configuration Tool or dynamically by calling the function XXX_create. This section describes objects created using the Configuration Tool. To create objects dynamically see section 2.2.8, Creating, Referencing, and Deleting Dynamically-Created DSP/BIOS Objects, page 2-10.

For typical DSP applications, most objects should be created with the Configuration Tool because they are used throughout program execution. A number of default objects are automatically defined in the configuration template. Creating objects with the Configuration Tool provides the following benefits:

- Improved access within DSP/BIOS Analysis Tools. The Execution Graph shows the names of objects created with the Configuration Tool. In addition, you can view statistics only for objects created with the Configuration Tool.

- Reduced code size. For a typical module, the XXX_create and XXX_delete functions contain 50% of the code required to implement the module. If you avoid using any calls to TSK_create and TSK_delete, the underlying code for these functions is not included in the application program. The same is true for other modules. By creating objects with the Configuration Tool you can dramatically reduce the size of your application program.
Note:
SYS_printf is probably the most memory intensive function in DSP/BIOS. Use the LOG functions instead of SYS_printf to make your application smaller.

- Improved run-time performance. In addition to saving code space, avoiding dynamic creation of objects reduces the time your program spends performing system setup.

Creating objects with the Configuration Tool has the following limitations:

- Objects are created whether or not they are needed. You can create objects dynamically if they will be used only as a result of infrequent run-time events.
- You cannot delete objects created with the Configuration Tool at run time using the XXX_delete functions.

Note:
No checks are performed to prevent an XXX_delete function from being used on an object created with the Configuration Tool. If a program attempts to delete an object that was not created dynamically, SYS_error is called.

Follow these steps to create an object using the Configuration Tool:

1) Right-click on a module and choose Insert XXX, where XXX is the name of the module. This adds a new object for the module. (You cannot create an object for the GBL, HWI, or SYS modules.)

2) Rename the object. Right-click on the name and choose Rename from the pop-up menu.

3) Right-click the icon next to the object and choose Properties to open the property sheet.

4) Change property settings and click OK. For help on specific properties, click Help in any property sheet.
2.2.5 Hierarchy Tree View

The Hierarchy Tree View of the Configuration Tool, as seen in the left pane of Figure 2-1, displays the instances of objects in alphabetic order.

Figure 2-1. Configuration Tool Hierarchy and Ordered Collection Views

2.2.6 Ordered Collection View

The Ordered Collection View displays the list of objects per module in the order the objects will be executed on the target as seen in Figure 2-1. To view the Ordered Collection View, right-click on the module name and select Ordered Collection View. The following objects can be listed in the Ordered Collection View:
Using the Configuration Tool

- CLK - Clock Manager
- PRD - Periodic Function Manager
- SWI - Software Task Manager
- TSK - Task Manager
- IDL - Idle Function Manager

The order of objects in the Ordered Collection View can be rearranged by dragging and dropping the object into its new position. For example, if you require the CLK0 object to execute immediately after the PRD_clock object, drag and drop CLK0 on top of the PRD_clock object. The dropped object is placed in the list immediately after the object that it is dropped upon, and will execute in that order. This is shown in Figure 2-1.

2.2.7 Referencing Static DSP/BIOS Objects Created with the Configuration Tool

Objects created using the Configuration Tool need to be declared using the extern variable declaration and must be defined outside of all function bodies. For example,

```c
extern far PIP_Obj inputObj;    /* C6000 devices */
```

or

```c
extern PIP_Obj inputObj;        /* C5000 devices */
```

The DSP/BIOS object is now visible in all functions that follow its definition in the program.

The Configuration Tool creates these declarations automatically in a file of the form program cfg.h, where program is the name of your application program. This file can be # included in your C files that reference the DSP/BIOS object.

Although DSP/BIOS itself is compiled using the small model, you can compile DSP/BIOS applications using either the C6000 compiler’s small model or any variation of the large model. (See the TMS320C6000 Optimizing Compiler User’s Guide.) In fact, you can mix compilation models within the application code provided all global data that is accessed by using a displacement relative to B14 is placed no more than 32K bytes away from the beginning of the .bss section.

DSP/BIOS uses the .bss section to store global data. However, objects created with the Configuration Tool are not placed in the .bss section. This maximizes your flexibility in the placement of application data. For example, the frequently accessed .bss can be placed in on-device memory while larger, less frequently accessed objects can be stored in external memory.
Using the Configuration Tool

The small model makes assumptions about the placement of global data in order to reduce the number of instruction cycles. If you are using the small model (the default compilation mode) to optimize global data access, your code can be modified to make sure that it references objects created with the Configuration Tool correctly.

There are four methods for dealing with this issue. These methods are described in the sections following and have the pros and cons as shown in Example 2-1.

Table 2-1. Methods of Referencing C6000 Global Objects

2.2.7.1 Referencing Static DSP/BIOS Objects in the Small Model (C6000 Platform Only)

In the small model, all compiled code accesses global data relative to a data page pointer register. The register B14 is treated as a read-only register by the compiler and is initialized with the starting address of the .bss section during program startup. Global data is assumed to be at a constant offset from the beginning of the .bss section and this section is assumed to be at most 32K bytes in length. Global data, therefore, can be accessed with a single instruction like the following:

\[
\text{LDW} \ \text{*}+\text{DP}(_\text{x}), \ A0 \ ; \text{load }_\text{x} \text{ into A0} \ (\text{DP} = \text{B14})
\]
Since objects created with the Configuration Tool are not placed in the .bss section, you must ensure that application code compiled with the small model references them correctly. There are three ways to do this:

- Declare static objects with the far keyword. The DSP/BIOS compiler supports this common extension to the C language. The far keyword in a data declaration indicates that the data is not in the .bss section.

  For example, to reference a PIP object called inputObj that was created with the Configuration Tool, declare the object as follows:

  ```c
  extern far PIP_Obj inputObj;
  if (PIP_getReaderNumFrames(&inputObj)) {
      ...
  }
  ```

- Create and initialize a global object pointer. You can create a global variable that is initialized to the address of the object you want to reference. All references to the object must be made using this pointer, to avoid the need for the far keyword. For example:

  ```c
  extern PIP_Obj inputObj;
  PIP_Obj *input = &inputObj; /* input MUST be a global variable */
  if (PIP_getReaderNumFrames(input)) {
      ...
  }
  ```

  Declaring and initializing the global pointer consumes an additional word of data (to hold the 32-bit address of the object).

  Also, if the pointer is a static or automatic variable this technique fails. The following code does not operate as expected when compiled using the small model:

  ```c
  extern PIP_Obj inputObj;
  static PIP_Obj *input = &inputObj; /* ERROR!!!! */
  if (PIP_getReaderNumFrames(input)) {
      ...
  }
  ```

- Place all objects adjacent to .bss. If all objects are placed at the end of the .bss section, and the combined length of the objects and the .bss data is less than 32K bytes, you can reference these objects as if they were allocated within the .bss section:

  ```c
  extern PIP_Obj inputObj;
  if (PIP_getReaderNumFrames(&inputObj)) {
      ...
  }
  ```
Using the Configuration Tool

You can guarantee this placement of objects by using the Configuration Tool as follows:

a) Declare a new memory segment by inserting a MEM object with the MEM Manager and setting its properties (i.e., the base and length); or use one of the preexisting data memory MEM objects.

b) Place all objects that are referenced by small model code in this memory segment.

c) Place Uninitialized Variables Memory (.bss) in this same segment by right-clicking on the MEM Manager and choosing Properties.

2.2.7.2 Referencing Static DSP/BIOS Objects in the Large Model (C6000 Platform Only)

In the large model, all compiled code accesses data by first loading the entire 32-bit address into an address register and then using the indirect addressing capabilities of the LDW instruction to load the data. For example:

```
MVKL  _x, A0     ; move low 16-bits of _x’s address into A0
MVKH  _x, A0     ; move high 16-bits of _x’s address into A0
LDW   *A0, A0    ; load _x into A0
```

Application code compiled with any of the large model variants is not affected by the location of static objects. If all code that directly references objects created with the Configuration Tool is compiled with any large model option, code can reference the objects as ordinary data:

```
extern PIP_Obj inputObj;
if (PIP_getReaderNumFrames(&inputObj)) {
    . . .
}
```

The -ml0 large model option is identical to small model except that all aggregate data is assumed to be far. This option causes all static objects to be assumed to be far objects but allows scalar types (such as int, char, long) to be accessed as near data. As a result, the performance degradation for many applications is quite modest.

2.2.8 Creating, Referencing, and Deleting Dynamically-Created DSP/BIOS Objects

You can create many, but not all, DSP/BIOS objects by calling the function XXX_create where XXX names a specific module. Some objects can only be created in the Configuration Tool. Each XXX_create function allocates memory for storing the object's internal state information, and returns a handle used to reference the newly-created object when calling other functions provided by the XXX module.
Most XXX_create functions accept as their last parameter a pointer to a structure of type XXX_Attrs which is used to assign attributes to the newly-created object. By convention, the object is assigned a set of default values if this parameter is NULL. These default values are contained in the constant structure XXX_ATTRS listed in the header files, enabling you to first initialize a variable of type XXX_Attrs and then selectively update its fields with application-dependent attribute values before calling XXX_create. Sample code that creates a dynamic object using the TSK_create is shown in Example 2-1.

Example 2-1. Creating and Referencing Dynamic Objects

```c
#include <tsk.h>
TSK_Attrs attrs;
TSK_Handle task;

attrs = TSK_ATTRS;
attrs.name = "reader";
attrs.priority = TSK_MINPRI;

task = TSK_create((Fxn)foo, &attrs);
```

The XXX_create function passes back a handle that is an address to the task's object. This handle is can then be passed as an argument when referencing, for example, deleting the object, as shown in Example 2-2. Objects created with XXX_create are deleted by calling the function XXX_delete. This frees the object's internal memory back to the system for later use.

Use the global constant XXX_ATTRS to copy the default values, update its fields, and pass as the argument to the XXX_create function.

Example 2-2. Deleting a Dynamic Object

```c
TSK_delete (task);
```

Dynamically-created DSP/BIOS objects allow for a program to adapt at runtime.
2.3 Files Used to Create DSP/BIOS Programs

When you save a configuration file for your program with the Configuration Tool, the following files are created. These files are described below. The numeric 62 is applicable to the C62x platform only. Replace the 62 in the extensions with 54, 55, or 64 depending on your platform.

- program.cdb
- programcfg.h54
- programcfg.s54
- programcfg.cmd
- programcfg.h
- programcfg_c.c

Figure 2-2 shows the files used to create DSP/BIOS programs. Files you write are represented with a white background; generated files are represented with a gray background. The word program represents the name of your project or program.

Figure 2-2. DSP/BIOS Program Creation Files

- program.c. Program source file containing the main function. You can also have additional .c source files and program .h files. For user functions, see section 2.8, User Functions Called by DSP/BIOS.

- *asm. Optional assembly source file(s). One of these files can contain an assembly language function called _main as an alternative to using a C or C++ function called main.
Files Used to Create DSP/BIOS Programs

- **module.h**: DSP/BIOS API header files for C or C++ programs. Your source files should include std.h and the header files for any modules the program uses.

- **module.h54**: DSP/BIOS API header files for assembly programs. Assembly source files should include the *.h54 header file for any module the assembly source uses.

- **program.obj**: Object file(s) compiled or assembled from your source file(s)

- ***.obj**: Object files for optional assembly source file(s)

- **program.cdb**: Configuration file, that stores configuration settings. This file is created by the Configuration Tool and used by both the Configuration Tool and the DSP/BIOS Analysis Tools.

- **programcfg.h54**: Header file generated by the Configuration Tool. This header file is included by the programcfg.s54 file.

- **programcfg.s54**: Assembly source generated by the Configuration Tool

- **programcfg.cmd**: Linker command file created by the Configuration Tool and used when linking the executable file. This file defines DSP/BIOS-specific link options and object names, and generic data sections for DSP programs (such as .text, .bss, .data, etc.).

- **programcfg.obj**: Object file created from the source file generated by the Configuration Tool.

- ***.cmd**: Optional linker command file(s) that contains additional sections for your program not defined by the Configuration Tool.

- **program.out**: An executable program for the target (fully compiled, assembled, and linked). You can load and run this program with Code Composer Studio commands.

- **programcfg.h**: File containing declarations of objects created with the Configuration Tool. It also contains the definition of the CSL_xxxx macro where xxxx is the Chip Type property of the Global Settings module.

- **programcfg.c.c**: File containing program code for CSL settings, generated automatically when a configuration file is saved. It # includes the programcfg.h file.

### 2.3.1 Files Used by the DSP/BIOS Analysis Tools

The following files are used by the DSP/BIOS Analysis Tools:

- **program.cdb**: The configuration file provides object names and other program information.

- **program.out**: The executable file provides symbol addresses and other program information.
2.4 Compiling and Linking Programs

You can build your DSP/BIOS executables using a Code Composer Studio project or using your own makefile. The Code Composer Studio software includes gmake.exe, the GNU make utility, and sample makefiles for gmake to build the tutorial examples.

2.4.1 Building With a Code Composer Studio Project

When building a DSP/BIOS application using a Code Composer Studio project, you must add the following files to the project in addition to your own source code files:

- **program.cdb.** The configuration file.
- **programcfg.cmd.** The linker command file.

Code Composer Studio software adds programcfg.s54 automatically.

In a DSP/BIOS application, programcfg.cmd is your project’s linker command file. This file already includes directives for the linker to use the appropriate libraries (e.g., bios.a54, rtdx.lib, rts5401.lib), so you do not need to add any of these library files to your project.

Code Composer Studio software automatically scans all dependencies in your project files, adding the necessary DSP/BIOS and RTDX header files for your configuration to your project’s include folder. Figure 2-3 shows a sample project files list.

Figure 2-3. Sample Code Composer Project Files List
For details on how to create a Code Composer Studio project and build an executable from it, refer to the *Code Composer Studio User’s Guide* or the online help.

For most DSP/BIOS applications the generated linker command file, `programcfg.cmd`, suffices to describe all memory segments and allocations. All DSP/BIOS memory segments and objects are handled by this linker command file. In addition, most commonly used sections (such as .text, .bss, .data, etc.) are already included in `programcfg.cmd`. Their locations (and sizes, when appropriate) can be controlled from the MEM Manager in the Configuration Tool. Figure 2-4 illustrates the Code Composer Studio properties dialog box.

In some cases the application can require an additional linker command file (`app.cmd`) describing application-specific sections that are not described in the linker command file generated by the Configuration Tool (`programcfg.cmd`).

*Figure 2-4. MEM Module Properties Panel*
2.4.2 Makefiles

As an alternative to building your program as a Code Composer Studio project, you can use a makefile.

In the following example, the C source code file is volume.c, additional assembly source is in load.asm, and the configuration file is volume.cdb. This makefile is for use with gmake, which is included with the Code Composer Studio software. You can find documentation for gmake on the product CD in PDF format. Adobe Acrobat Reader is included. This makefile and the source and configuration files mentioned are located in the volume2 subdirectory of the tutorial directory of Code Composer Studio distribution CD.

A typical makefile for compiling and linking a DSP/BIOS program is shown in Example 2-3. You can copy an example makefile to your program folder and modify the makefile as necessary.

Unlike the Code Composer Studio project, makefiles allow for multiple linker command files. If the application requires additional linker command files you can easily add them to the CMDS variable in the example makefile shown in Example 2-3. However, they must always appear after the programcfg.cmd linker command file generated by the Configuration Tool.
Example 2-3. Sample Makefile for a DSP/BIOS Program

```bash
# Makefile for creation of program named by the PROG variable
# The following naming conventions are used by this makefile:
#    <prog>.asm    - C54 assembly language source file
#    <prog>.obj    - C54 object file (compiled/assembled source)
#    <prog>.out    - C54 executable (fully linked program)
#    <prog>cfg.s54 - configuration assembly source file
#                  generated by Configuration Tool
#    <prog>cfg.h54 - configuration assembly header file
#                  generated by Configuration Tool
#    <prog>cfg.cmd - configuration linker command file
#                  generated by Configuration Tool

include $(TI_DIR)/c5400/bios/include/c54rules.mak

# Compiler, assembler, and linker options.
# -g enable symbolic debugging
CC54OPTS = -g
AS54OPTS =
# -q quiet run
LD54OPTS = -q

# Every BIOS program must be linked with:
#    $(PROG)cfg.o54 - object resulting from assembling
#    $(PROG)cfg.s54
#    $(PROG)cfg.cmd - linker command file generated by
#                  the Configuration Tool. If additional
#                  linker command files exist,
#                  $(PROG)cfg.cmd must appear first.

    @ echo removing object files and binaries ...
    @ remove -f *.obj *.out *.lst *.map
```

Program Generation 2-17
2.5 Using DSP/BIOS with the Run-Time Support Library

The linker command file generated by the Configuration Tool automatically includes directives to search the necessary libraries including a DSP/BIOS, RTDX, and a run-time support library. The run-time support library is created from rts.src, which contains the source code for the run-time support functions. These are standard ANSI functions that are not part of the C language (such as functions for memory allocation, string conversion, and string searches). A number of memory management functions that are defined within rts.src are also defined within the DSP/BIOS library. These are malloc, free, memalign, calloc, and realloc. The libraries support different implementations. For example, the DSP/BIOS versions are implemented with the MEM module and therefore make use of the DSP/BIOS API calls MEM_alloc and MEM_free. Because the DSP/BIOS library provides some of the same functionality found within the run-time support library, the DSP/BIOS linker command file includes a special version of the run-time support library called rtsbios that does not include the files shown in Table 2-2.

Table 2-2. Files Not Included in rtsbios

<td>autoinit.c</td>
</tr>
<tr>
<td></td>
<td></td>
<td>boot.c</td>
</tr>
</tbody>
</table>

In many DSP/BIOS projects, it is necessary to use the –x linker switch in order to force the rereading of libraries. For example, if printf references malloc and malloc has not already been linked in from the DSP/BIOS library, it forces the DSP/BIOS library to be searched again in order to resolve the reference to malloc.

The run-time support library implements printf with breakpoints. Depending on how often your application uses printf and the frequency of the calls, printf() can interfere with RTDX, thus affecting real-time analysis tools such as the Message Log and Statistics View, and preventing these tools from updating. This is because the printf breakpoint processing has higher priority processing than RTDX. It is therefore recommended to use LOG_printf in place of calls to printf wherever possible within DSP/BIOS applications.
Note:

It is recommended to use the DSP/BIOS library version of malloc, free, memalign, calloc and realloc within DSP/BIOS applications. When you are not referencing these functions directly in your application but call another run-time support function which references one or more of them, add `-u _symbol`, (for example, -u _malloc) to your linker options. The -u linker option introduces a symbol, such as malloc, as an unresolved symbol into the linker’s symbol table. This causes the linker to resolve the symbol from the DSP/BIOS library rather than the run-time support library. If in doubt, you can examine your map file for information on the library sources of your application.
2.6 DSP/BIOS Startup Sequence

When a DSP/BIOS application starts up, the calls or instructions in the boot.s54 (C54x platform), or autoinit.c and boot.snn (C6000 and C55x platforms) files determine the startup sequence. Compiled versions of these files are provided with the bios.ann and biosi.ann libraries and the source code is available on the distribution disks received with your product. The DSP/BIOS startup sequence, as specified in the source code of the boot files is shown below. You should not need to alter the startup sequence.

1) **Initialize the DSP.** A DSP/BIOS program starts at the C or C++ environment entry point c_int00. The reset interrupt vector is set up to branch to c_int00 after reset.

For the C54x platform, at the beginning of c_int00, the system stack pointer (SP) is set up to point to the end of .stack. Status registers such as st0 and st1 are also initialized.

At the beginning of c_int00 for the C55x platform, the data (user) stack pointer (XSP) and the system stack pointer (XSSP) are both set up to point to the bottom of the user and system stacks, respectively. Additionally, the XSP is aligned to an even address boundary.

For the C6000 platform, at the beginning of c_int00, the system stack pointer (B15) and the global page pointer (B14) are set up to point to the end of the stack section and the beginning of .bss, respectively. Control registers such as AMR, IER, and CSR are also initialized.

2) **Initialize the .bss from the .cinit records.** Once the stacks are set up, the initialization routine is called to initialize the variables from the .cinit records.

3) **Call BIOS_init to initialize the modules used by the application.**

   BIOS_init performs basic module initialization. BIOS_init invokes the MOD_init macro for each DSP/BIOS module used by the application. BIOS_init is generated by the Configuration Tool and is located in the programcfg.snn file.

   HWI_init sets up the ISTP and the interrupt selector registers, sets the NMIE bit in the IER on the C6000 platform, and clears the IFR on all platforms. See the **HWI Module Section** in the **TMS320 DSP/BIOS API Reference Guide** for your platform for more information.
DSP/BIOS Startup Sequence

Note:
When configuring an interrupt with the Configuration Tool, DSP/BIOS plugs in the corresponding ISR (interrupt service routine) into the appropriate location of the interrupt service table. However, DSP/BIOS does not enable the interrupt bit in IER. It is your responsibility to do this at startup or whenever appropriate during the application execution.

- **HST init** initializes the host I/O channel interface. The specifics of this routine depend on the particular implementation used for the host to target link. For example, in the C6000 platform, if RTDX is used, HST_init enables the bit in IER that corresponds to the hardware interrupt reserved for RTDX.

- **IDL init** calculates the idle loop instruction count. If the Auto calculate idle loop instruction count box was chosen in the Idle Function Manager in the Configuration Tool, IDL_init calculates the idle loop instruction count at this point in the startup sequence. The idle loop instruction count is used to calibrate the CPU load displayed by the CPU Load Graph (see section 3.4.2, The CPU Load, page 3-19).

4) **Process the .pinit table.** The .pinit table consists of pointers to initialization functions. For C++ programs, class constructors of global objects execute during .pinit processing.

5) **Call your program's main routine.** After all DSP/BIOS modules have completed their initialization procedures, your main routine is called. This routine can be written in assembly, C, C++ or a combination. Because the C compiler adds an underscore prefix to function names, this can be a C or C++ function called main or an assembly function called _main.

Since neither hardware nor software interrupts are enabled yet, you can take care of initialization procedures for your own application (such as calling your own hardware initialization routines) from the main routine.

6) **Call BIOS_start to start DSP/BIOS.** Like BIOS_init, BIOS_start is also generated by the Configuration Tool and is located in the programcfg.s.nnn file. BIOS_start is called after the return from your main routine. BIOS_start is responsible for enabling the DSP/BIOS modules and invoking the MOD_startup macro for each DSP/BIOS module. If the TSK Manager is enabled in the Configuration Tool, the call to BIOS_start does not return. For example:

- **CLK_startup** sets up the PRD register, enables the bit in the IER (C6000 platform) or the IMR (C5400 platform) for the timer chosen in the CLK Manager, and finally starts the timer. (This macro is only expanded if you enable the CLK Manager in the Configuration Tool.)
DSP/BIOS Startup Sequence

- PIP_startup calls the notifyWriter function for each created pipe object.
- SWI_startup enables software interrupts.
- HWI_startup enables hardware interrupts by setting the GIE bit in the CSR on the C6000 platform or clearing the INTM bit in the ST1 register on the C5400 platform.
- TSK_startup enables the task scheduler and launches the highest priority task that is ready to run. If the application has no tasks that are currently ready, the TSK_idle executes and calls IDL_loop. Once TSK_startup is called, the application begins and thus execution does not return from TSK_startup or from BIOS_start. TSK_startup runs only if the Task Manager is enabled in the Configuration Tool.

7) Execute the idle loop. You can enter the idle loop in one of two ways. In the first way, the Task Manager is enabled. The Task scheduler runs TSK_idle which calls IDL_loop. In the second way, the Task Manager is disabled and thus the call to BIOS_start returns and a call to IDL_loop follows. By calling IDL_loop, the boot routine falls into the DSP/BIOS idle loop forever. At this point, hardware and software interrupts can occur and preempt idle execution. Since the idle loop manages communication with the host, data transfer between the host and the target can now take place.

2.6.1 Advanced Startup: C5500 Platform Only

On the C5500 platform, the architecture allows the software to reprogram the start of the vector tables (256 bytes in overall length) by setting the registers IVPD and IVPH. By default, the hardware reset loads 0xFFFF to both these registers and the reset vector is fetched from location 0xFF – FF00. To move the vector tables to a different location, it is necessary to write the desired address into IVPD and IVPH after the hardware reset and then do a software reset, at which time the new values in IVPD and IVPH take effect.

The macro HWI_init loads the configured vector table address into IVPD and IVPH but must be followed by a software reset to actually bring the new IVPD and IVPH into effect.
The C5500 platform also allows for three possible stack modes (see Table 2-3). To configure the processor in any of the non-default modes, the user is required to set bits 28 and 29 to the reset vector location appropriately using the Code Composer Studio debugger tool and then to apply a software reset. For more information, please see the TMS320C55x DSP CPU Reference Guide.

2.7 Using C++ with DSP/BIOS

DSP/BIOS applications can be written in C++. An understanding of issues regarding C++ and DSP/BIOS can help to make C++ application development proceed smoothly. These issues concern memory management, name mangling, calling class methods from the Configuration Tool, and special considerations for class constructors and destructors.

2.7.1 Memory Management

The functions new and delete are the C++ operators for dynamic memory allocation and deallocation. Within DSP/BIOS applications, these operators are reentrant because they are implemented with the DSP/BIOS memory management functions MEM_alloc and MEM_free. However, memory management functions require that the calling thread obtain a lock to memory before proceeding if the requested lock is already held by another thread, blocking results. Therefore, new and delete should be used by TSK objects only.

The functions new and delete are defined by the run-time support library, not the DSP/BIOS library. Since the DSP/BIOS library is searched first, some applications can result in a linker error stating that there are undefined symbols that were first referenced within the rtsbios (the run-time support) library. This linker error is avoided by using the -x linker option which forces libraries to be searched again in order to resolve undefined references. See section 2.5, Using DSP/BIOS with the Run-Time Support Library for more information.

2.7.2 Name Mangling

The C++ compiler implements function overloading, operator overloading, and type-safe linking by encoding a function's signature in its link-level name. The process of encoding the signature into the linkname is referred to as name mangling. Name mangling could potentially interfere with a DSP/BIOS application since you use function names within the Configuration Tool to refer to functions declared in your C++ source files. To prevent name mangling and thus to make your functions recognizable within the Configuration Tool, it is necessary to declare your functions in an extern C block as shown in the code fragment of Example 2-4.
Example 2-4. Declaring Functions in an Extern C Block

```c
extern "C" {
    Void function1();
    Int function2();
}
```

This allows you to refer to the functions within the Configuration Tool (preceded by an underscore, as with other C function names). For example, if you had an SWI object which should run function1() every time that the SWI posts, you would enter _function1 into the function property of that SWI object.

Functions declared within the extern C block are not subject to name mangling. Since function overloading is accomplished through name mangling, function overloading has limitations for functions that are called from within the Configuration Tool. Only one version of an overloaded function can appear within the extern C block. The code in Example 2-5 would result in an error.

Example 2-5. Function Overloading Limitation

```c
extern "C" {
    Int addNums(Int x, Int y);
    Int addNums(Int x, Int y, Int z); // error, only one version
    of addNums is allowed
}
```

While you can use name overloading in your DSP/BIOS C++ applications, only one version of the overloaded function can be called from the Configuration Tool.

Default parameters is a C++ feature that is not available for functions called from the Configuration Tool. C++ allows you to specify default values for formal parameters within the function declaration. However, a function called from the Configuration Tool must provide parameter values. If no values are specified, the actual parameter values are undefined.

2.7.3 Calling Class Methods from the Configuration Tool

Often, the function that you want to reference within the Configuration Tool is the member function of a class object. It is not possible to call these member functions directly from the Configuration Tool, but it is possible to accomplish the same action through wrapper functions. By writing a wrapper function which accepts a class instance as a parameter, you can invoke the class member function from within the wrapper.
A wrapper function for a class method is shown in Example 2-6.

**Example 2-6. Wrapper Function for a Class Method**

```c
Void wrapper (SampleClass myObject)
{
    myObject->method();
}
```

Any additional parameters that the class method requires can be passed to the wrapper function.

### 2.7.4 Class Constructors and Destructors

Any time that a C++ class object is instantiated, the class constructor executes. Likewise, any time that a class object is deleted, the class destructor is called. Therefore, when writing constructors and destructors, you should consider the times at which the functions are expected to execute and tailor them accordingly. It is important to consider what type of thread will be running when the class constructor or destructor is invoked.

Various guidelines apply to which DSP/BIOS API functions can be called from different DSP/BIOS threads (tasks, software interrupts, and hardware interrupts). For example, memory allocation APIs such as MEM_alloc and MEM_calloc cannot be called from within the context of a software interrupt. Thus, if a particular class is instantiated by a software interrupt, its constructor must avoid performing memory allocation. Similarly, it is important to keep in mind the time at which a class destructor is expected to run. Not only does a class destructor execute when an object is explicitly deleted, but also when a local object goes out of scope. You need to be aware of what type of thread is executing when the class destructor is called and make only those DSP/BIOS API calls that are appropriate for that thread. For further information on function callability, see the *TMS320 DSP/BIOS API Reference Guide* for your platform.
2.8 User Functions Called by DSP/BIOS

User functions called by DSP/BIOS objects (IDL, TSK, SWI, PIP, PRD, and CLK objects) need to follow specific conventions in order to ensure that registers are used properly and that values are preserved across function calls.

On the C6x and C55x platforms, all user functions called by DSP/BIOS objects need to conform to C compiler register conventions for their respective platforms. This applies to functions written both in C and assembly languages.

The compiler distinguishes between C and assembly functions by assuming that all C function names are preceded by an underscore, and assembly function names are not preceded by an underscore. On the C54x platform, this distinction becomes especially important because C and assembly functions conform to two different sets of rules. Functions that are preceded by an underscore (this includes C functions and any assembly functions whose names are preceded by an underscore) must conform to the C compiler conventions. On the C54x platform, assembly functions (functions that are not preceded by an underscore) must conform to the following rules:

- The first argument is passed in register AR2
- The second argument is passed in register A
- The return value is passed in register A

Note:

The above rules do not apply to user functions called by TSK objects. All user functions (both C and assembly) called by TSK objects follow C register conventions.

On the C54x platform when a C function (or an assembly function whose function name is preceded by an underscore) is executing, the CPL (Compiler Mode) bit is required to be set. When an assembly function (one whose name is not preceded by an underscore) begins executing, the CPL bit is clear and must be clear upon return.

For more information on C register conventions, see the optimizing compiler user’s guide for your platform.
2.9 Calling DSP/BIOS APIs from Main

The main routine in a DSP/BIOS application is for user initialization purposes such as configuring a peripheral, or enabling individual hardware interrupts. It is important to recognize that main does not fall into any of the DSP/BIOS threads types (HWI, SWI, TSK, or IDL), and that when program execution reaches main, not all of the DSP/BIOS initialization is complete. This is because DSP/BIOS initialization takes place in two phases: during BIOS_init which runs before main, and during BIOS_start which runs after your program returns from main.

Certain DSP/BIOS API calls should not be made from the main routine, because the BIOS_start initialization has not yet run. BIOS_start is responsible for enabling global interrupts, configuring and starting the timer, and enabling the schedulers so that DSP/BIOS threads can start executing. Therefore, DSP/BIOS calls that are not appropriate from main are APIs which assume hardware interrupts and the timer are enabled, or APIs that make scheduling calls that could block execution. For example, functions such as CLK_gettime and CLK_gettime should not be called from main because the timer is not running. HWI_disable and HWI_enable should not be called because hardware interrupts are not globally enabled. Potentially blocking calls, such as SEM_pend or MBX_pend, should not be called from main because the scheduler is not initialized. Scheduling calls such as TSK_disable, TSK_enable, SWI_disable, or SWI_enable are also not appropriate within main.

BIOS_init, which runs before main, is responsible for initialization of the MEM module. Therefore, it is okay to call dynamic memory allocation functions from main. Not only are the MEM module functions allowed (MEM_alloc, MEM_free, etc.), but APIs for dynamic creation and deletion of DSP/BIOS objects, such as TSK_create and TSK_delete, are also allowed.

While blocking calls are not permitted from main, scheduling calls that make a DSP/BIOS thread ready to run are permitted. These are calls such as SEM_post or SWI_post. If such a call is made from main, the readied thread is scheduled to run after the program returns from main and BIOS_start finishes executing.

See the TMS320 DSP/BIOS API Reference Guide for your platform for more information on a particular DSP/BIOS function call. The Constraints and Calling Context sections indicates if the API cannot be called from main.
DSP/BIOS provides both explicit and implicit ways to perform real-time program analysis. These mechanisms are designed to have minimal impact on the application's real-time performance.

3.1 Real-Time Analysis

Real-time analysis is the analysis of data acquired during real-time operation of a system. The intent is to easily determine whether the system is operating within its design constraints, is meeting its performance targets, and has room for further development.

3.1.1 Real-Time Versus Cyclic Debugging

The traditional debugging method for sequential software is to execute the program until an error occurs. You then stop the execution, examine the program state, insert breakpoints, and reexecute the program to collect information. This kind of cyclic debugging is effective for non-real-time sequential software. However, cyclic debugging is rarely as effective in real-time systems because real-time systems are characterized by continuous operation, nondeterministic execution, and stringent timing constraints.

The DSP/BIOS instrumentation APIs and the DSP/BIOS Analysis Tools are designed to complement cyclic debugging tools to enable you to monitor real-time systems as they run. This real-time monitoring data lets you view the real-time system operation so that you can effectively debug and performance-tune the system.

3.1.2 Software Versus Hardware Instrumentation

Software monitoring consists of instrumentation code that is part of the target application. This code is executed at run time, and data about the events of interest is stored in the target system's memory. Thus, the instrumentation code uses both the computing power and memory of the target system.

The advantage of software instrumentation is that it is flexible and that no additional hardware is required. Unfortunately, because the instrumentation is part of the target application, performance and program behavior can be affected. Without using a hardware monitor, you face the problem of finding a balance between program perturbation and recording sufficient information. Limited instrumentation provides inadequate detail, but excessive instrumentation perturbs the measured system to an unacceptable degree.

DSP/BIOS provides a variety of mechanisms that allow you to control precisely the balance between intrusion and information gathered. In addition, the DSP/BIOS instrumentation operations all have fixed, short execution times. Since the overhead time is fixed, the effects of instrumentation are known in advance and can be factored out of measurements.
3.2 Instrumentation Performance

When all implicit DSP/BIOS instrumentation is enabled, the CPU load increases less than one percent in a typical application. Several techniques have been used to minimize the impact of instrumentation on application performance:

- Instrumentation communication between the target and the host is performed in the background (IDL) thread, which has the lowest priority, so communicating instrumentation data does not affect the real-time behavior of the application.

- From the host, you can control the rate at which the host polls the target. You can stop all host interaction with the target if you want to eliminate all unnecessary external interaction with the target.

- The target does not store Execution Graph or implicit statistics information unless tracing is enabled. You also have the ability to enable or disable the explicit instrumentation of the application by using the TRC module and one of the reserved trace masks (TRC_USER0 and TRC_USER1).

- Log and statistics data are always formatted on the host. The average value for an STS object and the CPU load are computed on the host. Computations needed to display the Execution Graph are performed on the host.

- LOG, STS, and TRC module operations are very fast and execute in constant time, as shown in the following list:
  - LOG_printf and LOG_event: approximately 30 instructions
  - STS_add: approximately 30 instructions
  - STS_delta: approximately 40 instructions
  - TRC_enable and TRC_disable: approximately four instructions
  - LOG_printf and LOG_event: approximately 25 instructions
  - STS_add: approximately 10 instructions
  - STS_delta: approximately 15 instructions
  - TRC_enable and TRC_disable: approximately four instructions
  - LOG_printf and LOG_event: approximately 32 instructions
  - STS_add: approximately 18 instructions
  - STS_delta: approximately 21 instructions
  - TRC_enable and TRC_disable: approximately six instructions

- Each STS object uses only eight or four words of data memory, for the C5000 platform or the C6000 platform, respectively. This means that the host always transfers the same number of words to upload data from a statistics object.
Statistics are accumulated in 32-bit variables on the target and in 64-bit variables on the host. When the host polls the target for real-time statistics, it resets the variables on the target. This minimizes space requirements on the target while allowing you to keep statistics for long test runs.

You can specify the buffer size for LOG objects. The buffer size affects the program’s data size and the time required to upload log data.

For performance reasons, implicit hardware interrupt monitoring is disabled by default. When disabled, there is no effect on performance. When enabled, updating the data in statistics objects consumes between 20 and 30 instructions per interrupt for each interrupt monitored.

### 3.2.1 Instrumented Versus Non-instrumented Kernel

It is possible to disable support for the kernel instrumentation by changing the global properties of the application. Within the Configuration Tool, the Global Settings module has a property called Enable Real Time Analysis. By unchecking this checkbox, you can achieve optimal code size and execution speed. This is accomplished by linking with a DSP/BIOS library that does not support the implicit instrumentation. However, this also has the effect of removing support for DSP/BIOS Analysis Tools and explicit instrumentation such as the LOG, TRC, and STS module APIs.

The Table 3-1 presents examples of code size increases when working with the instrumented versus non-instrumented kernel. These figures provide a general idea of the amount of code increase that can be expected when working with the instrumented kernel. Table 3-1 uses as samples two example projects that are shipped with Code Composer Studio software which utilize many of the DSP/BIOS features. By including DSP/BIOS modules, the example applications incorporate the instrumentation code. Therefore the following numbers are representative of the amount of code size incurred by the instrumentation, and are not affected by the size or variations among users’ applications. The first example, Slice, contains the TSK, SEM, and PRD modules, while the second example, Echo, uses the PRD and SWI modules. Neither example application is specifically designed for minimizing code size.

For information on DSP/BIOS kernel performance benchmarks, including a comparison of the instrumented versus non-instrumented kernels’ performances, see Application Report SPRA662, *DSP/BIOS Timing Benchmarks on the TMS320C6000 DSP.*

3.3 Instrumentation APIs

Effective instrumentation requires both operations that gather data and operations that control the gathering of data in response to program events. DSP/BIOS provides the following three API modules for data gathering:

- **LOG (Event Log Manager).** Log objects capture information about events in real time. System events are captured in the system log. You can create additional logs using the Configuration Tool. Your program can add messages to any log.

- **STS (Statistics Object Manager).** Statistics objects capture count, maximum, and total values for any variables in real time. Statistics about SWI (software interrupt), PRD (period), HWI (hardware interrupt), PIP (pipe), and TSK (task) objects can be captured automatically. In addition, your program can create statistics objects to capture other statistics.

- **HST (Host Channel Manager).** The host channel objects described in Chapter 7, Input/Output Overview and Pipes, allow a program to send raw data streams to the host for analysis.

LOG and STS provide an efficient way to capture subsets of a real-time sequence of events that occur at high frequencies or a statistical summary of data values that vary rapidly. The rate at which these events occur or values change may be so high that it is either not possible to transfer the entire sequence to the host (due to bandwidth limitations) or the overhead of transferring this sequence to the host would interfere with program operation. DSP/BIOS provides the TRC (Trace Manager) module for controlling the data gathering mechanisms provided by the other modules. The TRC module controls which events and statistics are captured either in real time by the target program or interactively through the DSP/BIOS Analysis Tools.

Controlling data gathering is important because it allows you to limit the effects of instrumentation on program behavior, ensure that LOG and STS objects contain the necessary information, and start or stop recording of events and data values at run time.

### 3.3.1 Explicit versus Implicit Instrumentation

The instrumentation API operations are designed to be called explicitly by the application. The LOG module operations allow you to explicitly write messages to any log. The STS module operations allow you to store statistics about data variables or system performance. The TRC module allows you to enable or disable log and statistics tracing in response to a program event.
Instrumentation APIs

The LOG and STS APIs are also used internally by DSP/BIOS to collect information about program execution. These internal calls in DSP/BIOS routines provide implicit instrumentation support. As a result, even applications that do not contain any explicit calls to the DSP/BIOS instrumentation APIs can be monitored and analyzed using the DSP/BIOS Analysis Tools. For example, the execution of a software interrupt is recorded in a LOG object called LOG_system.

In addition, worst-case ready-to-completion times for software interrupts and overall CPU load are accumulated in STS objects. The occurrence of a system tick is also shown in the Execution Graph. See section 3.3.4.2, Control of Implicit Instrumentation, page 3-15, for more information about what implicit instrumentation can be collected.

3.3.2 Event Log Manager (LOG Module)

This module manages LOG objects, which capture events in real time while the target program executes. You can use the Execution Graph, or view user-defined logs orchestrated with the Configuration Tool.

User-defined logs contain any information your program stores in them using the LOG_event and LOG_printf operations. You can view messages in these logs in real time with the Message Log as shown in Figure 3-1. To access the Message Log, select DSP/BIOS→Message Log.

Figure 3-1. Message Log Dialog Box

The Execution Graph, which is the system log, can also be viewed as a graph of the activity for each program component.

A log can be either fixed or circular. This distinction is important in applications that enable and disable logging programmatically (using the TRC module operations as described in section 3.4.4, Trace Manager (TRC Module), page 3-13).
Instrumentation APIs

- **Fixed.** The log stores the first messages it receives and stops accepting messages when its message buffer is full. As a result, a fixed log stores the first events that occur since the log was enabled.

- **Circular.** The log automatically overwrites earlier messages when its buffer is full. As a result, a circular log stores the last events that occur.

You create LOG objects using the Configuration Tool with which you assign properties such as the length and location of the message buffer.

You can specify the length of each message buffer in words. Individual messages use four words of storage in the log’s buffer. The first word holds a sequence number. The remaining three words of the message structure hold event-dependent codes and data values supplied as parameters to operations such as `LOG_event`, which appends new events to a LOG object.

As shown in Figure 3-2, LOG buffers are read from the target and stored in a much larger buffer on the host. Records are marked empty as they are copied up to the host.

**Figure 3-2. LOG Buffer Sequence**

LOG_printf uses the fourth word of the message structure for the offset or address of the format string (for example, `%d, %d`). The host uses this format string and the two remaining words to format the data for display. This minimizes both the time and code space used on the target since the actual `printf` operation (and the code to perform the operation) are handled on the host.

LOG_event and LOG_printf both operate on logs with interrupts disabled. This allows hardware interrupts and other threads of different priorities to write to the same log without having to worry about synchronization.
Using the RTA Control Panel Properties dialog box as shown in Figure 3-3, you can control how frequently the host polls the target for log information. To access the RTA Control Panel select DSP/BIOS→RTA Control Panel. Right-click on the RTA Control Panel and choose the Property Page to set the refresh rate. If you set the refresh rate to 0, the host does not poll the target for log information unless you right-click on a log window and choose Refresh Window from the pop-up menu. You can also use the pop-up menu to pause and resume polling for log information.

Figure 3-3.  RTA Control Panel Properties Dialog Box.

Log messages shown in a message log window are numbered (in the left column of the trace window) to indicate the order in which the events occurred. These numbers are an increasing sequence starting at 0. If your log never fills up, you can use a smaller log size. If a circular log is not long enough or you do not poll the log often enough, you may miss some log entries that are overwritten before they are polled. In this case, you see gaps in the log message numbers. You may want to add an additional sequence number to the log messages to make it clear whether log entries are being missed.

The online help in the Configuration Tool describes LOG objects and their parameters. See LOG Module in the TMS320 DSP/BIOS API Reference Guide for your platform for information on the LOG module API calls.
3.3.3 Statistics Object Manager (STS Module)

This module manages statistics objects, which store key statistics while a program runs.

You create individual statistics objects using the Configuration Tool. Each STS object accumulates the following statistical information about an arbitrary 32-bit wide data series:

- **Count.** The number of values on the target in an application-supplied data series
- **Total.** The arithmetic sum of the individual data values on the target in this series
- **Maximum.** The largest value already encountered on the target in this series
- **Average.** Using the count and total, the Statistics View Analysis Tool calculates the average on the host

Calling the STS_add operation updates the statistics object of the data series being studied. For example, you might study the pitch and gain in a software interrupt analysis algorithm or the expected and actual error in a closed-loop control algorithm.

DSP/BIOS statistics objects are also useful for tracking absolute CPU use of various routines during execution. By bracketing appropriate sections of the program with the STS_set and STS_delta operations, you can gather real-time performance statistics about different portions of the application.

You can view these statistics in real time with the Statistics View as shown in Figure 3-4. To access the Statistics View, select DSP/BIOS → Statistics View.

![Figure 3-4. Statistics View Panel](image)
Although statistics are accumulated in 32-bit variables on the target, they are accumulated in 64-bit variables on the host. When the host polls the target for real-time statistics, it resets the variables on the target. This minimizes space requirements on the target while allowing you to keep statistics for long test runs. The Statistics View can optionally filter the data arithmetically before displaying it as shown in Figure 3-5.

**Figure 3-5. Target/Host Variable Accumulation**

By clearing the values on the target, the host allows the values displayed to be much larger without risking lost data due to values on the target wrapping around to 0. If polling of STS data is disabled or very infrequent, there is a possibility that the STS data wraps around, resulting in incorrect information.

While the host clears the values on the target automatically, you can clear the 64-bit objects stored on the host by right-clicking on the STS Data window and choosing Clear from the shortcut menu.

The host read and clear operations are performed with interrupts disabled to allow any thread to update any STS object reliably. For example, an HWI function can call STS_add on an STS object and no data is missing from any STS fields.

This instrumentation process provides minimal intrusion into the target program. A call to STS_add requires approximately 20 instructions on the C5000 platform and 18 instructions on the C6000 platform. Similarly, an STS object uses only eight or four words of data memory on the C5000 or C6000 platforms, respectively. Data filtering, formatting, and computation of the average is done on the host.

You can control the polling rate for statistics information with the RTA Control Panel Property Page. If you set the polling rate to 0, the host does not poll the target for information about the STS objects unless you right-click on the Statistics View window and choose Refresh Window from the pop-up menu.
3.3.3.1 Statistics About Varying Values

STS objects can be used to accumulate statistical information about a time series of 32-bit data values.

For example, let \( P_i \) be the pitch detected by an algorithm on the \( i \)th frame of audio data. An STS object can store summary information about the time series \( \{P_i\} \). The following code fragment includes the current pitch value in the series of values tracked by the STS object:

```c
pitch = 'do pitch detection'
STS_add(&stsObj, pitch);
```

The Statistics View displays the number of values in the series, the maximum value, the total of all values in the series, and the average value.

3.3.3.2 Statistics About Time Periods

In any real-time system, there are important time periods. Since a period is the difference between successive time values, STS provides explicit support for these measurements.

For example, let \( T_i \) be the time taken by an algorithm to process the \( i \)th frame of data. An STS object can store summary information about the time series \( \{T_i\} \). The following code fragment illustrates the use of CLK_gethtime (high-resolution time), STS_set, and STS_delta to track statistical information about the time required to perform an algorithm:

```c
STS_set(&stsObj, CLK_gethtime());
'do algorithm'
STS_delta(&stsObj, CLK_gethtime());
```

STS_set saves the value of CLK_gethtime as the contents of the previous value field (set value) in the STS object. STS_delta subtracts this set value from the new value it is passed. The result is the difference between the time recorded before the algorithm started and after it was completed; that is, the time it took to execute the algorithm \( (T_i) \). STS_delta then invokes STS_add and passes this result as the new contents of the previous value field to be tracked.

The host can display the count of times the algorithm was performed, the maximum time to perform the algorithm, the total time performing the algorithm, and the average time.

The set value is the fourth component of an STS object. It is provided to support statistical analysis of a data series that consist of value differences, rather than absolute values.
3.3.3.3 Statistics About Value Differences

Both STS_set and STS_delta update the contents of the previous value field in an STS object. Depending on the call sequence, you can measure specific value differences or the value difference since the last STS update. Example 3-1 shows code for gathering information about differences between specific values. Figure 3-6 shows current values when measuring differences from the base value.

Example 3-1. Gathering Information About Differences in Values

```c
STS_set(&sts, targetValue); /* T_0 */
"processing"
STS_delta(&sts, currentValue); /* T_1 */
"processing"
STS_delta(&sts, currentValue); /* T_2 */
"processing"
STS_delta(&sts, currentValue); /* T_3 */
"processing"
```

Figure 3-6. Current Value Deltas From One STS_set
Example 3-2 gathers information about a value’s difference from a base value. Figure 3-7 illustrates the current value when measuring differences from a base value.

Example 3-2. Gathering Information About Differences from Base Value

```c
STS_set(&sts, baseValue);
"processing"
STS_delta(&sts, currentValue);
STS_set(&sts, baseValue);
"processing"
STS_delta(&sts, currentValue);
STS_set(&sts, baseValue);
"processing"
STS_delta(&sts, currentValue);
STS_set(&sts, baseValue);
"processing"
```

Figure 3-7. Current Value Deltas from Base Value

The online help in the Configuration Tool describes statistics objects and their parameters. See STS Module in the TMS320 DSP/BIOS API Reference Guide for your platform for information on the STS module API calls.
3.3.4 Trace Manager (TRC Module)

The TRC module allows an application to enable and disable the acquisition of analysis data in real time. For example, the target can use the TRC module to stop or start the acquisition of data when it discovers an anomaly in the application’s behavior.

Control of data gathering is important because it allows you to limit the effects of instrumentation on program behavior, ensure that LOG and STS objects contain the necessary information, and start or stop recording of events and data values at run time.

For example, by enabling instrumentation when an event occurs, you can use a fixed log to store the first n events after you enable the log. By disabling tracing when an event occurs, you can use a circular log to store the last n events before you disable the log.

3.3.4.1 Control of Explicit Instrumentation

You can use the TRC module to control explicit instrumentation as shown in this code fragment:

```c
if (TRC_query(TRC_USER0) == 0) {
    // LOG or STS operation
}
```

**Note:**

TRC_query returns 0 if all trace types in the mask passed to it are enabled, and is not 0 if any trace types in the mask are disabled.

The overhead of this code fragment is just a few instruction cycles if the tested bit is not set. If an application can afford the extra program size required for the test and associated instrumentation calls, it is very practical to keep this code in the production application simplifying the development process and enabling field diagnostics. This is, in fact, the model used within the DSP/BIOS instrumented kernel.

3.3.4.2 Control of Implicit Instrumentation

The TRC module manages a set of trace bits that control the real-time capture of implicit instrumentation data through logs and statistics objects. For greater efficiency, the target does not store log or statistics information unless tracing is enabled. (You do not need to enable tracing for messages explicitly written with LOG_printf or LOG_event and statistics added with STS_add or STS_delta.)
Instrumentation APIs

DSP/BIOS defines constants for referencing specific trace bits as shown in Figure 3-2. The trace bits allow the target application to control when to start and stop gathering system information. This can be important when trying to capture information about a specific event or combination of events.

Table 3-2. TRC Constants:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Tracing Enabled/Disabled</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>TRC_LOGCLK</td>
<td>Logs low-resolution clock interrupts</td>
<td>off</td>
</tr>
<tr>
<td>TRC_LOGPRD</td>
<td>Logs system ticks and start of periodic functions</td>
<td>off</td>
</tr>
<tr>
<td>TRC_LOGSWI</td>
<td>Logs posting, start, and completion of software interrupt functions</td>
<td>off</td>
</tr>
<tr>
<td>TRC_LOGTSK</td>
<td>Logs events when a task is made ready, starts, becomes blocked, resumes execution, and terminates. This constant also logs semaphore posts.</td>
<td>off</td>
</tr>
<tr>
<td>TRC_STSHWI</td>
<td>Gathers statistics on monitored register values within HWIs</td>
<td>off</td>
</tr>
<tr>
<td>TRC_STSPIP</td>
<td>Counts the number of frames read from or written to data pipe</td>
<td>off</td>
</tr>
<tr>
<td>TRC_STSPRD</td>
<td>Gathers statistics on the number of ticks elapsed during execution of periodic functions</td>
<td>off</td>
</tr>
<tr>
<td>TRC_STSSWI</td>
<td>Gathers statistics on number of instruction cycles or time elapsed from post to completion of software interrupt</td>
<td>off</td>
</tr>
<tr>
<td>TRC_STSTSK</td>
<td>Gather statistics on length of TSK execution from when a task is made ready to run until a call to TSK_deltatime() is made; measured in timer interrupt units or CLK ticks.</td>
<td>off</td>
</tr>
<tr>
<td>TRC_USER0</td>
<td>Enables or disables sets of explicit instrumentation actions. You can use TRC_query to check the settings of these bits and either perform or omit calls based on the result. DSP/BIOS does not use or set these bits.</td>
<td>off</td>
</tr>
<tr>
<td>TRC_USER1</td>
<td>Simultaneously starts or stops gathering all enabled types of tracing. This bit must be set in order for any implicit instrumentation to be performed. This bit is usually set at run time on the host with the RTA Control Panel.</td>
<td>off</td>
</tr>
<tr>
<td>TRC_GBLHOST</td>
<td>Controls implicit instrumentation. This bit must also be set in order for any implicit instrumentation to be performed, and can only be set by the target program.</td>
<td>on</td>
</tr>
</tbody>
</table>

Note: Updating Task Statistics

If TSK_deltatime is not called by a task, its statistics will never be updated in the Statistics View, even if TSK accumulators are enabled in the RTA Control Panel.

TSK statistics are handled differently than other statistics because TSK functions typically run an infinite loop that blocks while waiting for other threads. In contrast, HWI and SWI functions run to completion without blocking. Because of this difference, DSP/BIOS allows programs to identify the "beginning" of a TSK function’s processing loop by calling TSK_settime and the "end" of the loop by calling TSK_deltatime.
You can enable and disable these trace bits in the following ways:

- From the host, use the RTA Control Panel as shown in Figure 3-8. This panel allows you to adjust the balance between information gathering and time intrusion at run time. By disabling various implicit instrumentation types, you lose information but reduce the overhead of processing.
  
  You can control the refresh rate for trace state information by right-clicking on the Property Page of the RTA Control Panel. If you set the refresh rate to 0, the host does not poll the target for trace state information unless you right-click on the RTA Control Panel and choose Refresh Window from the pop-up menu. Initially, all boxes on the RTA Control Panel are checked by default.

Figure 3-8. RTA Control Panel Dialog Box.

- From the target code, enable and disable trace bits using the TRC_enable and TRC_disable operations, respectively. For example, the following C code disables tracing of log information for software interrupts and periodic functions:

  ```c
  TRC_disable(TRC_LOGSWI | TRC_LOGPRD);
  ```

  For example, in an overnight run you might be looking for a specific circumstance. When it occurs, your program can perform the following statement to turn off all tracing so that the current instrumentation information is preserved:

  ```c
  TRC_disable(TRC_GBLTARG);
  ```

  Any changes made by the target program to the trace bits are reflected in the RTA Control Panel. For example, you could cause the target program to disable the tracing of information when an event occurs. On the host, you can simply wait for the global target enable check box to be cleared and then examine the log.
3.4 Implicit DSP/BIOS Instrumentation

The instrumentation needed to allow the DSP/BIOS Analysis Tools to display the Execution Graph, system statistics, and CPU load are built automatically into a DSP/BIOS program to provide implicit instrumentation. You can enable different components of DSP/BIOS implicit instrumentation by using the RTA Control Panel Analysis Tool in Code Composer, as described in section 3.4.4.2, Control of Implicit Instrumentation, page 3-15.

DSP/BIOS instrumentation is efficient—when all implicit instrumentation is enabled, the CPU load increases less than one percent for a typical application. See section 3.2, Instrumentation Performance, page 3-3, for details about instrumentation performance.

3.4.1 The Execution Graph

The Execution Graph is a special graph used to display information about SWI, PRD, TSK, SEM and CLK processing. You can enable or disable logging for each of these object types at run time using the TRC module API or the RTA Control Panel in the host. Semaphore posts on the Execution Graph are controlled by enabling or disabling TSK logging. The Execution Graph window, as shown in Figure 3-9, shows the Execution Graph information as a graph of the activity of each object.

Figure 3-9. Execution Graph Window
CLK and PRD events are shown to provide a measure of time intervals within the Execution Graph. Rather than timestamping each log event, which is expensive (because of the time required to get the timestamp and the extra log space required), the Execution Graph simply records CLK events along with other system events. As a result, the time scale on the Execution Graph is not linear.

In addition to SWI, TSK, SEM, PRD, and CLK events, the Execution Graph shows additional information in the graphical display. Assertions are indications that either a real-time deadline has been missed or an invalid state has been detected (either because the system log has been corrupted or the target has performed an illegal operation). The LOG_message state, which has the color green associated with it, appears on the Assertions trace line for LOG_message calls made by the user’s application. Errors generated by internal log calls are shown in red on the Assertions trace line. Red boxes on the Assertions trace indicate a break in the information gathered from the system log.

See section 4.1.5, Yielding and Preemption, page 4-8, for details on how to interpret the Execution Graph information in relation to DSP/BIOS program execution.

3.4.2 The CPU Load

The CPU load is defined as the percentage of instruction cycles that the CPU spends doing application work. That is, the percentage of the total time that the CPU is:

- Running hardware interrupts, software interrupts, tasks, or periodic functions
- Performing I/O with the host
- Running any user routine

When the CPU is not doing any of these, it is considered idle, including when the CPU is in a power-save or hardware-idle mode. To view the CPU Load Graph window, as seen in Figure 3-10, select DSP/BIOS→CPU Load Graph.
All CPU activity is divided into work time and idle time. To measure the CPU load over a time interval $T$, you need to know how much time during that interval was spent doing application work ($t_w$) and how much of it was idle time ($t_i$). From this you can calculate the CPU load as follows:

$$\text{CPU load} = \frac{t_w}{T} \times 100$$

Since the CPU is always either doing work or in idle it is represented as follows:

$$T = t_w + t_i$$

You can rewrite this equation:

$$\text{CPU load} = \frac{t_w}{t_w + t_i} \times 100$$

You can also express CPU load using instruction cycles rather than time intervals:

$$\text{CPU load} = \frac{c_w}{c_w + c_i} \times 100$$

### 3.4.2.1 Measuring the CPU Load

In a DSP/BIOS application, the CPU is doing work when any of the following are occurring:

- hardware interrupts are serviced
- software interrupts and periodic functions are run
- task functions are run
- user functions are executed from the idle loop
- HST channels are transferring data to the host
- real-time analysis data is uploaded to the DSP/BIOS Analysis Tools
When the CPU is not performing any of those activities, it is going through the idle loop, executing the IDL_cpuLoad function, and calling the other DSP/BIOS IDL objects. In other words, the CPU idle time in a DSP/BIOS application is the time that the CPU spends doing the routine in Example 3-3.

To measure the CPU load in a DSP/BIOS application over a time interval \( T \), it is sufficient to know how much time was spent going through the loop, shown in Figure 3-3, and how much time was spent doing application work.

**Example 3-3. The Idle Loop**

```plaintext
'Idle_loop:
   Perform IDL_cpuLoad
   Perform all other IDL functions (user or system functions)
   Goto IDL_loop'
```

Over a period of time \( T \), a CPU with \( M \) MIPS (million instructions per second) executes \( M \times T \) instruction cycles. Of those instruction cycles, \( c_w \) are spent doing application work. The rest are spent executing the idle loop shown in Example 3-3. If the number of instruction cycles required to execute this loop once is \( l_1 \), the total number of instruction cycles spent executing the loop is \( N \times l_1 \) where \( N \) is the number of times the loop is repeated over the period \( T \). Hence, you have total instruction cycles equals work instruction cycles plus idle instruction cycles.

\[
MT = c_w + Nl_1
\]

From this expression you can rewrite \( c_w \) as:

\[
c_w = MT - Nl_1
\]

**3.4.2.2 Calculating the Application CPU Load**

Using the previous equations, you can calculate the CPU load in a DSP/BIOS application as:

\[
CPU_{load} = \frac{c_w}{MT} \times 100 = \frac{MT - Nl_1}{MT} \times 100 = \left(1 - \frac{Nl_1}{MT}\right) \times 100
\]

To calculate the CPU load you need to know \( l_1 \) and the value of \( N \) for a chosen time interval \( T \), over which the CPU load is being measured.

The IDL_cpuLoad object in the DSP/BIOS idle loop updates an STS object, IDL_busyObj, that keeps track of the number of times the IDL_loop runs, and the time as kept by the DSP/BIOS high-resolution clock (see section 4.8, *Timers, Interrupts, and the System Clock*, page 4-61). This information is used by the host to calculate the CPU load according to the equation above.
The host uploads the STS objects from the target at the polling rate set in the RTA Control Panel Property Page. The information contained in IDL_busyObj is used to calculate the CPU load. The IDL_busyObj count provides a measure of N (the number of times the idle loop ran). The IDL_busyObj maximum is not used in CPU load calculation. The IDL_busyObj total provides the value T in units of the high-resolution clock.

To calculate the CPU load you still need to know $l_1$ (the number of instruction cycles spent in the idle loop). When the Auto calculate idle loop instruction count box is checked in the Idle Function Manager in the Configuration Tool, DSP/BIOS calculates $l_1$ at initialization from BIOS_init.

The host uses the values described for N, T, $l_1$, and the CPU MIPS to calculate the CPU load as follows:

$$CPU_{load} = \left[ 1 - \frac{Nl_1}{MT} \right] \times 100$$

### 3.4.3 Hardware Interrupt Count and Maximum Stack Depth

You can track the number of times an individual HWI function has been triggered by using the Configuration Tool to set the monitor parameter for an HWI object to monitor the stack pointer. An STS object is created automatically for each hardware ISR that is monitored as shown in Figures 3-11 and 3-12.

**Figure 3-11. Monitoring Stack Pointers (C5000 platform)**
Implicit DSP/BIOS Instrumentation

Figure 3-12. Monitoring Stack Pointers (C6000 platform)

For hardware interrupts that are not monitored, there is no overhead—control passes directly to the HWI function. For interrupts that are monitored, control first passes to a stub function generated by the Configuration Tool. This function reads the selected data location, passes the value to the selected STS operation, and finally branches to the HWI function.

The enable HWI accumulations check box in the RTA Control Panel must be selected in order for HWI function monitoring to take place. If this type of tracing is not enabled, the stub function branches to the HWI function without updating the STS object.

The number of times an interrupt is triggered is recorded in the Count field of the STS object. When the stack pointer is monitored, the maximum value reflects the maximum position of the top of the system stack when the interrupt occurs. This can be useful for determining the system stack size needed by an application. To determine the maximum depth of the stack, follow these steps (see Figure 3-13):

1) Using the Configuration Tool right-click on the HWI object and select Properties, and change the monitor field to Stack Pointer. You should also change the operation field to STS_add(–*addr) and leave the other default settings as they are.

These changes give you the minimum value of the stack pointer in the maximum field of the STS object. This is the top of the stack, since the stack grows downward in memory.

2) Link your program and use the nmti program, which is described in Chapter 2, Utility Programs in the TMS320 DSP/BIOS API Reference Guide for your platform, to find the address of the end of the system stack. Or, you can find the address in Code Composer by using a Memory window or the map file to find the address referenced by the GBL_stackend symbol. (This symbol references the top of the stack.)
Implicit DSP/BIOS Instrumentation

3) Run your program and view the STS object that monitors the stack pointer for this HWI function in the Statistics View window.

4) Subtract the minimum value of the stack pointer (maximum field in the STS object) from the end of the system stack to find the maximum depth of the stack.

The Kernel Object View displays stack information for all targets. (See section 3.5, Kernel/Object View Debugger)

Figure 3-13. Calculating Used Stack Depth

```
used stack depth = (GBL_stackend - min(SP))
STS_add(~addr) = min(SP)
```

3.4.4 Monitoring Variables

In addition to counting hardware interrupt occurrences and monitoring the stack pointer, you can monitor any register or data value each time a hardware interrupt is triggered.

This implicit instrumentation can be enabled for any HWI object. Such monitoring is not enabled by default. The performance of your interrupt processing is not affected unless you enable this type of instrumentation in the Configuration Tool. The statistics object is updated each time hardware interrupt processing begins. Updating such a statistics object consumes between 20 and 30 instructions per interrupt for each interrupt monitored.
Implicit DSP/BIOS Instrumentation

To enable implicit HWI instrumentation:

1) Open the properties window for any HWI object and choose a register to monitor in the monitor field.

You can monitor any of the variables shown in Table 3-3, or you can choose to monitor nothing. When you choose to monitor a variable, the Configuration Tool automatically creates an STS object which stores the statistics for the variable.

Table 3-3. Variables that can be Monitored with HWI

</tbody>
</table>

2) Set the operation parameter to the STS operation you want to perform on this value.

You can perform one of the operations shown in Table 3-4 on the value stored in the variable you select. For all these operations, the number of times this hardware interrupt has been executed is stored in the count field (see Figure 3-5). The max and total values are stored in the STS object on the target. The average is computed on the host.
Table 3-4. STS Operations and Their Results

<table>
<thead>
<tr>

</tr>
<tr>
<td>STS_add( -*addr )</td>
<td>Negates the data value or register value and stores the maximum and total. As a result, the value stored as the maximum is the negated minimum value. The total and average are the negated total and average values.</td>
</tr>
<tr>
<td>STS_delta( -*addr)</td>
<td>Negates the data value or register value and compares the data value or register value to the prev property of the STS object (or a value set programmatically with STS_set). Stores the maximum and total differences. As a result, the value stored as the maximum is the negated minimum difference.</td>
</tr>
<tr>
<td>STS_add(</td>
<td>*addr</td>
</tr>
<tr>
<td>STS_delta(</td>
<td>*addr</td>
</tr>
</tbody>
</table>

3) You may also set the properties of the corresponding STS object to filter the values of this STS object on the host.

For example, you might want to watch the top of the system stack to see whether the application is exceeding the allocated stack size. The top of the system stack is initialized to 0xBEEF on the C5000 platform and to 0xC0FFEE on the C6000 platform when the program is loaded. If this value ever changes, the application has either exceeded the allocated stack or some error has caused the application to overwrite the application’s stack.

One way to watch for the allocated stack size being exceeded is to follow these steps:

1) In the Configuration Tool, enable implicit instrumentation on any regularly occurring HWI function. Right-click on the HWI object, select Properties, and change the monitor field to Top of SW Stack with STS_delta(*addr) as the operation.

2) Set the prev property of the corresponding STS object to 0xBEEF on the C5000 platform or to 0xC0FFEE on the C6000 platform.
3) Load your program in Code Composer and use the Statistics View to view the STS object that monitors the stack pointer for this HWI function.

4) Run your program. Any change to the value at the top of the stack is seen as a non-zero total (or maximum) in the corresponding STS object.

### 3.4.5 Interrupt Latency

Interrupt latency is the maximum time between the triggering of an interrupt and when the first instruction of the HWI executes. You can measure interrupt latency for the timer interrupt by following the appropriate steps for your platform:

1) Configure the HWI_TINT object to monitor the timer register.

2) Set the operation parameter to STS_add(-*addr).

3) Set the host operation parameter of the HWI_TINT_STS object to A*x + B. Set A to 1 and B to the value of the PRD Register (shown in the global CLK properties list).

**Note:**

It is not possible at this time to calculate interrupt latency for the C5500 platform using DSP/BIOS because the C55x timer access is outside data space.

4) Configure the HWI object specified by the CPU Interrupt property of the CLK Manager to monitor a Data Value.

5) Set the addr parameter to the address of the timer counter register for the on-device timer used by the CLK Manager.

3) Set the type to unsigned.

4) Set the operation parameter to STS_add(*addr).

5) Set the Host Operation parameter of the corresponding STS object, HWI_INT14_STS, to A * X + B. Set A to 4 and B to 0.

The STS objects HWI_TINT_STS (C5000 platform) or HWI_INT14_STS (C6000 platform) then display the maximum time (in instruction cycles) between when the timer interrupt was triggered and when the Timer Counter Register was able to be read. This is the interrupt latency experienced by the timer interrupt. The interrupt latency in the system is at least as large as this value.
3.5 Kernel/Object View Debugger

The Kernel/Object View debug tool allows a view into the current configuration, state, and status of the DSP/BIOS objects currently running on the target. To start Kernel/Object View in Code Composer Studio software, go to DSP/BIOS → Kernel/Object View as shown in Figure 3-14.

Figure 3-14. Selecting The Kernel/Object View Debugger.

There are six pages of object data available to you: Kernel, Tasks, Mailboxes, Semaphores, Memory, and Software Interrupts. The Kernel/Object View can display names that are labels for other items on the target because some labels share memory locations. In this case you can see a name that does not match the configuration. If a label is not available for a memory location, a name is automatically generated and is indicated with angle brackets (for example, <task1>).

All pages have a Refresh button and a Disable button in the upper left corner. When the Refresh button is clicked on any page, it updates all the pages concurrently so that the data remains consistent on all pages. If the refresh button is pressed while the target is running, the target is halted, the data is collected, and then the target is restarted. All changes in displayed data are indicated by red text. If a stack overflow is detected, the data field containing the peak used value turns red, and yellow text flags the error.

The Disable button allows you to disable the Kernel/Object View tool while you single-step through code or run through multiple break points. Since the tool takes some time to read all of the kernel data, you can disable it on occasion to step through to some critical code. The tool is enabled by pressing the refresh button or by changing pages to another object view. When the tool is disabled, Kernel Mode is set to 'Enabled' and will displace other information that may have previously appeared in that field. This is shown in Figure 3-15. The six pages of the Kernel/Object View are described in the sections that follow.
3.5.1 Kernel

The kernel page (select the tab labeled KNL) shows system-wide information as shown in Figure 3-16.

Figure 3-15. The Disabled Message

Figure 3-16. The Kernel Page Dialog Box

The Kernel page fields and other information are as follows:

- **Mode.** The value in this field indicates the current operating mode of the target. When Kernel appears, it indicates that the program is currently executing inside DSP/B IOS while Application indicates that the application is executing.
- **Target.** The Target field indicates the target processor and whether it is an emulator or simulator.

- **Time.** This is the current value of the clock that is used for timer functions and alarms for tasks. The clock is set up during configuration (PRD_clk) in CLK - Clock Manager. This is only used when tasks are enabled in the Task Manager (TSK). When tasks are disabled, the time field remains zero.

- **System Stack.** The four boxes on the right edge indicate system stack information.

- **Tasks Blocked with Timers Running.** This list contains all tasks that are currently blocked and have timers running. The timers are used to unblock the tasks in the case that they are not made ready by any other means. The tasks are unblocked with a semaphore, a message in a mailbox and so on.

### 3.5.2 Tasks

The tasks page (select the tab labeled TSK) shows all task information as illustrated in Figure 3-17.

**Figure 3-17. The Task Page Dialog Box**

The task page fields and other information are as follows:

- **Task(s).** The value in this field indicates the number of tasks present in the currently operating system. The number of lines of information in the main information field is equal to the value in this field.
Kernel/Object View Debugger

- **Name (Handle)**. This is the task name and handle. The name is taken from the label for statically configured objects and is generated for dynamically created objects. The label matches the name in the task manager configuration. The handle is the address on the target.

- **State**. The current state of the task: Ready, Running, Blocked, or Terminated.

- **Priority**. This is the task's priority as set in the configuration or as set by the API. Valid priorities are 0 through 15.

- **Peak Used**. This is the peak stack usage for the task. Since it shows the maximum ever used by the task, a warning appears if this value ever matches the Stack Size value in the next column. A warning is indicated when this field is red and the text is yellow.

- **Stack Size**. This is the stack size.

- **Previous**. Yes indicates that this task was the one running before the current task started.

- **Start/End**. This indicates the beginning and end of the stack in memory.

### 3.5.3 Mailboxes

The mailboxes page (select the tab labeled MBX) shows all mailbox information as illustrated in Figure 3-18.

**Figure 3-18. The Mailboxes Page Dialog Box**

The mailboxes page fields and other information are as follows:

- **Mailbox(es)**. The value in this field indicates the number of mailboxes present in the currently operating system. The number of lines of information in the main information field is equal to the value in this field.
Kernel/Object View Debugger

- **Name (Handle)**. This is the mailbox name and handle. The name is taken from the label for statically configured objects and is generated for dynamically created objects. The label matches the name in the MBX Manager configuration. The handle is the address on the target.

- **Msgs/Max**. The first number is the current number of messages that the mailbox contains. The second number is the maximum number of messages that the mailbox can hold. The maximum matches the value set in the configuration.

- **Tasks Pending**. This is the number of tasks currently blocked waiting to read a message from the mailbox. If the value is non-zero you can click on the number to see the list of tasks.

- **Tasks Posting**. This is the number of tasks currently blocked waiting to write a message to the mailbox. If the value is non-zero you can click on the number to see the list of tasks as shown in Figure 3-19.

- **Msg Size**. This is the size of each message in the processor’s minimum addressable data units (MADUs). This matches the values set during configuration or creation. MADUs are equivalent to a 16-bit word in the data address space of the processor on the C54x and C55x platforms and to an 8-bit word on the C6x platforms.

- **Segment**. This is the memory segment number.

*Figure 3-19. Viewing a List of Tasks Currently Blocked*
3.5.4 Semaphores

The semaphores page (select the tab labeled SEM) shows all semaphore information as illustrated in Figure 3-20.

Figure 3-20. The Semaphores Page Dialog Box

<table>
<thead>
<tr>
<th>Name (Handle)</th>
<th>Count</th>
<th>Tasks Pending</th>
</tr>
</thead>
<tbody>
<tr>
<td>sem0 0x80000050</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>sem1 0x80000078</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>sem2 0x00000BA0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

The semaphores page fields and other information are as follows:

- **Semaphore(s)**. The value in this field indicates the number of semaphores present in the currently operating system. The number of lines of information in the main information field is equal to the value in this field.

- **Name (Handle)**. This is the semaphore name and handle. The name is taken from the label for statically configured objects and is generated for dynamically created objects. The label matches the name in the SEM Manager configuration. The handle is the address on the target.

- **Count**. This is the current semaphore count. This is the number of pends that can occur before blocking.

- **Tasks Pending**. This is the current number of tasks pending on the semaphore. If the value is non-zero you can click on the number to see a list of tasks that are pending as shown in Figure 3-21.
3.5.5 Memory

The memory page (select the tab labeled MEM) shows all memory heap information as illustrated in Figure 3-22.

Figure 3-22. The Memory Page Dialog Box

The memory page fields and other information are as follows:

- **Heap(s)**. The value in this field indicates the number of heaps present in the currently operating system. The number of lines of information in the main information field is equal to the value in this field.
- **Name**. This is the memory segment that the heap is allocated from as configured.
Max Contiguous. This is the maximum amount of contiguous memory that is free to allocate in the heap.

Free. This is the total amount of memory that is free to allocate in the heap. If this value is zero a warning will be given. A warning is indicated when this field is red and the text is yellow.

Size (Start/End). This is the heap size and the starting and ending locations in memory.

Used. This is the amount of memory that is allocated from the heap. If this value is equal to the size, a warning is given. A warning is indicated when this field is red and the text is yellow.

Segment. This is the memory segment.

3.5.6 Software Interrupts

The software interrupts page (select the tab labeled SWI) shows all software interrupt information.

Figure 3-23. The Software Interrupts Page Dialog Box

The software interrupts page fields and other information are as follows:

Software Interrupt(s). The value in this field indicates the number of software interrupts present in the currently operating system. The number of lines of information in the main information field is equal to the value in this field.

Name (Handle). This is the software interrupt name and handle. The name is taken from the label for statically configured objects and is generated for dynamically created objects. The label matches the name
Kernel/Object View Debugger

in the SWI Manager configuration. The handle is the address on the target.

- **State**. This is the software interrupt’s current state. Valid states are Inactive, Ready, or Running.

- **Priority**. This is the software interrupt’s priority as set in the configuration or during creation. Valid priorities are 0 through 15.

- **Mailbox**. This is the software interrupt’s current mailbox value.

- **Fxns (arg0, arg1) / Fxn Handle**: This is the software interrupt’s function and arguments as set in the configuration or during creation. The handle is the address on the target. The two function names, indicated by the angle brackets that surround the name, are functions that are generated by DSP/BIOS.
3.6 Instrumentation for Field Testing

The embedded DSP/BIOS run-time library and DSP/BIOS Analysis Tools support a new generation of testing and diagnostic tools that interact with programs running on production systems. Since DSP/BIOS instrumentation is so efficient, your production program can retain explicit instrumentation for use with manufacturing tests and field diagnostic tools, which can be designed to interact with both implicit and explicit instrumentation.

3.7 Real-Time Data Exchange

Real-Time Data Exchange (RTDX) provides real-time, continuous visibility into the way DSP applications operate in the real world. The RTDX plug-ins allow system developers to transfer data between a host computer and DSP devices without interfering with the target application. The data can be analyzed and visualized on the host using any OLE automation client. This shortens development time by giving you a realistic representation of the way your system actually operates.

RTDX consists of both target and host components. A small RTDX software library runs on the target DSP. The DSP application makes function calls to this library’s API in order to pass data to or from it. This library makes use of a scan-based emulator to move data to or from the host platform via a JTAG interface. Data transfer to the host occurs in real time while the DSP application is running.

On the host platform, an RTDX host library operates in conjunction with Code Composer Studio. Displays and analysis tools communicate with RTDX via an easy-to-use COM API to obtain the target data and/or to send data to the DSP application. Designers can use their choice of standard software display packages, including:

- LabVIEW from National Instruments
- Real-Time Graphics Tools from Quinn-Curtis
- Microsoft Excel

Alternatively, you can develop your own Visual Basic or Visual C++ applications. Instead of focusing on obtaining the data, you can concentrate on designing the display to visualize the data in the most meaningful way.
3.7.1 RTDX Applications

RTDX is well suited for a variety of control, servo, and audio applications. For example, wireless telecommunications manufacturers can capture the outputs of their vocoder algorithms to check the implementations of speech applications.

Embedded control systems also benefit from RTDX. Hard disk drive designers can test their applications without crashing the drive with improper signals to the servo-motor. Engine control designers can analyze changing factors (like heat and environmental conditions) while the control application is running.

For all of these applications, you can select visualization tools that display information in a way that is most meaningful to you.

3.7.2 RTDX Usage

RTDX can be used with or without DSP/BIOS. The target programs in the volume4, hostio1, and hostio2 examples in the c:\ti\tutorial folder tree use RTDX in conjunction with various DSP/BIOS modules. The examples in the c:\ti\tutorial\target\rtdx folder tree and the c:\ti\examples\target\rtdx folder tree use RTDX without DSP/BIOS.

RTDX is available with the PC-hosted Code Composer Studio running Windows 98, or Windows NT version 4.0. RTDX in simulation is supported.

This document assumes that the reader is familiar with C, Visual Basic or Visual C++, and OLE/ActiveX programming.

3.7.3 RTDX Flow of Data

Code Composer Studio data flow between the host (PC) and the target (TI processor) as shown in Figure 3-24.
3.7.3.1 Target to Host Data Flow

To record data on the target, you must declare an output channel and write data to it using routines defined in the user interface. This data is immediately recorded into an RTDX target buffer defined in the RTDX target library. The data in the buffer is then sent to the host via the JTAG interface.

The RTDX host library receives this data from the JTAG interface and records it. The host records the data into either a memory buffer or to an RTDX log file (depending on the RTDX host recording mode specified).

The data can be retrieved by any host application that is an OLE automation client. Some typical examples of OLE-capable host applications are:

- Visual Basic applications
- Visual C++ applications
- Lab View
- Microsoft Excel

Typically, an RTDX OLE automation client is a display that allows you to visualize the data in a meaningful way.

3.7.3.2 Host to Target Data Flow

For the target to receive data from the host, you must first declare an input channel and request data from it using routines defined in the user interface. The request for data is recorded into the RTDX target buffer and sent to the host via the JTAG interface.
An OLE automation client can send data to the target using the OLE Interface. All data to be sent to the target is written to a memory buffer within the RTDX host library. When the RTDX host library receives a read request from the target application, the data in the host buffer is sent to the target via the JTAG interface. The data is written to the requested location on the target in real time. The host notifies the RTDX target library when the operation is complete.

3.7.3.3 RTDX Target Library User Interface

The user interface provides the safest method of exchanging data between a target application and the RTDX host library.

The data types and functions defined in the user interface handle the following functions:

- Enable a target application to send data to the RTDX host library
- Enable a target application to request data from the RTDX host library
- Provide data buffering on the target. A copy of your data is stored in a target buffer prior to being sent to the host. This action helps ensure the integrity of the data and minimizes real-time interference.
- Provide interrupt safety. You can call the routines defined in the user interface from within interrupt handlers.
- Ensure correct utilization of the communication mechanism. It is a requirement that only one datum at a time can be exchanged between the host and target using the JTAG interface. The routines defined in the user interface handle the timing of calls into the lower-level interfaces.

3.7.3.4 RTDX Host OLE Interface

The OLE interface describes the methods that enable an OLE automation client to communicate with the RTDX host library.

The functions defined in the OLE interface:

- Enable an OLE automation client to access the data that was recorded in an RTDX log file or is being buffered by the RTDX Host Library
- Enable an OLE automation client to send data to the target via the RTDX host library
3.7.4 RTDX Modes

The RTDX host library provides the following modes of receiving data from a target application:

- **Non-continuous.** The data is written to a log file on the host. Noncontinuous mode should be used when you want to capture a finite amount of data and record it in a log file.

- **Continuous.** The data is simply buffered by the RTDX host library; it is not written to a log file. Continuous mode should be used when you want to continuously obtain and display the data from a DSP application, and you don’t need to store the data in a log file.

**Note:**

To drain the buffer(s) and allow data to continuously flow up from the target, the OLE automation client must read from each target output channel on a continual basis. Failure to comply with this constraint may cause data flow from the target to cease, thus reducing the data rate, and possibly resulting in channels being unable to obtain data. In addition, the OLE automation client should open all target output channels on startup to avoid data loss to any of the channels.

3.7.5 Special Considerations When Writing Assembly Code

The RTDX functionality in the user library interface can be accessed by a target application written in assembly code.

3.7.6 Target Buffer Size

The RTDX target buffer is used to temporarily store data that is waiting to be transferred to the host. You may want to reduce the size of the buffer if you are transferring only a small amount of data. Alternately, you may need to increase the size of the buffer if you are transferring blocks of data larger than the default buffer size.

Using the Configuration Tool you can change the RTDX buffer size by right-clicking on the RTDX module and selecting Properties.
3.7.7 Sending Data From Target to Host or Host to Target

The user library interface provides the data types and functions for:

- Sending data from the target to the host
- Sending data from the host to the target

The following data types and functions are defined in the header file rtdx.h. They are available via DSP/BIOS or standalone.

- Declaration Macros
  - RTDX_CreateInputChannel
  - RTDX_CreateOutputChannel

- Functions
  - RTDX_channelBusy
  - RTDX_disableInput
  - RTDX_disableOutput
  - RTDX_enableOutput
  - RTDX_enableInput
  - RTDX_read
  - RTDX_readNB
  - RTDX_sizeofInput
  - RTDX_write

- Macros
  - RTDX_isInputEnabled
  - RTDX_isOutputEnabled

See the *TMS320 DSP/BIOS API Reference Guide* for your platform for detailed descriptions of all RTDX functions.
This chapter describes the types of threads a DSP/BIOS program can use, their behavior, and their priorities during program execution.

4.1 Overview of Thread Scheduling

Many real-time DSP applications must perform a number of seemingly unrelated functions at the same time, often in response to external events such as the availability of data or the presence of a control signal. Both the functions performed and when they are performed are important.

These functions are called threads. Different systems define threads either narrowly or broadly. Within DSP/BiOS, the term is defined broadly to include any independent stream of instructions executed by the DSP. A thread is a single point of control that can contain a subroutine, an interrupt service routine (ISR), or a function call.

DSP/BiOS enables your applications to be structured as a collection of threads, each of which carries out a modularized function. Multithreaded programs run on a single processor by allowing higher-priority threads to preempt lower-priority threads and by allowing various types of interaction between threads, including blocking, communication, and synchronization.

Real-time application programs organized in such a modular fashion—as opposed to a single, centralized polling loop, for example—are easier to design, implement, and maintain.

DSP/BiOS provides support for several types of program threads with different priorities. Each thread type has different execution and preemption characteristics. The thread types (from highest to lowest priority) are:

- Hardware interrupts (HWI), which includes CLK functions
- Software interrupts (SWI), which includes PRD functions
- Tasks (TSK)
- Background thread (IDL)

These thread types are described briefly in the following section and discussed in more detail in the rest of this chapter.

4.1.1 Types of Threads

The four major types of threads in a DSP/BiOS program are:

- **Hardware interrupts (HWI).** Triggered in response to external asynchronous events that occur in the DSP environment. An HWI function (also called an interrupt service routine or ISR) is executed after a hardware interrupt is triggered in order to perform a critical task that is subject to a hard deadline. HWI functions are the threads with the highest priority in a DSP/BiOS application. HWIs should be used for application tasks that need to run at frequencies approaching 200 kHz, and that need to be completed within deadlines of 2 to 100 microseconds. See section 4.2, *Hardware Interrupts*, page 4-11, for details about hardware interrupts.
Software interrupts (SWI). Patterned after hardware interrupt (HWIs). While HWIs are triggered by a hardware interrupt, software interrupts are triggered by calling SWI functions from the program. Software interrupts provide additional priority levels between hardware interrupts and TSKs. SWIs handle threads subject to time constraints that preclude them from being run as tasks, but whose deadlines are not as severe as those of hardware ISRs. Like HWIs, SWI's threads always run to completion. Software interrupts should be used to schedule events with deadlines of 100 microseconds or more. SWIs allow HWIs to defer less critical processing to a lower-priority thread, minimizing the time the CPU spends inside an interrupt service routine, where other HWIs can be disabled. See section 4.3, Software Interrupts, page 4-20, for details about software interrupts.

Tasks (TSK). Tasks have higher priority than the background thread and lower priority than software interrupts. Tasks differ from software interrupts in that they can be suspended during execution until necessary resources are available. DSP/BIOS provides a number of structures that can be used for inter task communication and synchronization. These structures include queues, semaphores, and mailboxes. See section 4.4, Tasks, page 4-34, for details about tasks.

Background thread. Executes the idle loop (IDL) at the lowest priority in a DSP/BIOS application. After main returns, a DSP/BIOS application calls the startup routine for each DSP/BIOS module and then falls into the idle loop. The idle loop is a continuous loop that calls all functions for the IDL objects. Each function must wait for all others to finish executing before it is called again. The idle loop runs continuously except when it is preempted by higher-priority threads. Only functions that do not have hard deadlines should be executed in the idle loop. See section 4.5, The Idle Loop, page 4-47, for details about the background thread.

There are several other kinds of functions that can be performed in a DSP/BIOS program. These are performed within the context of one of the thread types in the previous list.

Clock (CLK) functions. Triggered at the rate of the on-device timer interrupt. By default, these functions are triggered by a hardware interrupt and are performed as HWI functions. See section 4.8, Timers, Interrupts, and the System Clock, page 4-61, for details.

Periodic (PRD) functions. Performed based on a multiple of either the on-device timer interrupt or some other occurrence. Periodic functions are a special type of software interrupt. See section 4.9, Periodic Function Manager (PRD) and the System Clock, page 4-68, for details.

Data notification functions. Performed when you use pipes (PIP) or host channels (HST) to transfer data. The functions are triggered when a frame of data is read or written to notify the writer or reader. These functions are performed as part of the context of the function that called PIP_alloc, PIP_get, PIP_free, or PIP_put.
4.1.2 Choosing Which Types of Threads to Use

The type and priority level you choose for each thread in an application program has an impact on whether the threads are scheduled on time and executed correctly. The Configuration Tool makes it easy to change a thread from one type to another.

Here are some rules for deciding which type of object to use for each task to be performed by a program:

- **SWI or TSK versus HWI.** Perform only critical processing within hardware interrupt service routines. HWIs can run at frequencies approaching 200 kHz. Use software interrupts or tasks for events with deadlines around 100 microseconds or more. Your HWI functions should post software interrupts or tasks to perform lower-priority processing. Using lower-priority threads minimizes the length of time interrupts are disabled (interrupt latency), allowing other hardware interrupts to occur.

- **SWI versus TSK.** Use software interrupts if functions have relatively simple interdependencies and data sharing requirements. Use tasks if the requirements are more complex. While higher-priority threads can preempt lower priority threads, only tasks can be suspended to wait for another event, such as resource availability. Tasks also have more options than SWIs when using shared data. All input needed by a software interrupt's function should be ready when the program posts the SWI. The SWI object's mailbox structure provides a way to determine when resources are available. SWIs are more memory efficient because they all run from a single stack.

- **IDL.** Create background functions to perform noncritical housekeeping tasks when no other processing is necessary. IDL functions do not typically have hard deadlines. Instead, they run whenever the system has unused processor time.

- **CLK.** Use CLK functions when you want a function to be triggered directly by a timer interrupt. These functions run as HWI functions and should take minimal processing time. The default CLK object, PRD_clock, causes a tick for the periodic functions. You can add additional CLK objects to run at the same rate. However, you should minimize the time required to perform all CLK functions because they run as HWI functions.

- **PRD.** Use PRD functions when you want a function to run at a rate based on a multiple of the on-device timer's low-resolution rate or another event (such as an external interrupt). These functions run as SWI functions.

- **PRD versus SWI.** All PRD functions run at the same SWI priority, so one PRD function cannot preempt another. However, PRD functions can post lower-priority software interrupts for lengthy processing routines. This ensures that the PRD_swi software interrupt can preempt those routines when the next system tick occurs and PRD_swi is posted again.
4.1.3 A Comparison of Thread Characteristics

Table 4-1 provides a comparison of the thread types supported by DSP/BIOS.

Table 4-1. Comparison of Thread Characteristics

<table>

</tr>
</tbody>
</table>

Notes:
1) If you disable the TSK Manager in the Property dialog for the TSK Manager, IDL threads use the system stack.
2) See section 4.3.7, Saving Registers During Software Interrupt Preemption, page 4-31, for a list of saved registers.
3) HWI objects cannot be created dynamically because they correspond to DSP interrupts. However, interrupt functions can be changed at run time.
4) When a HWI function calls HWI_enter, it can pass a bitmask that indicates which interrupts to enable while the HWI function runs. An enabled interrupt can preempt the HWI function even if the enabled interrupt has a lower priority than the current interrupt.

**Notes:**

1. If you disable the TSK Manager in the Property dialog for the TSK Manager, IDL threads use the system stack.
2. See section 4.3.7, *Saving Registers During Software Interrupt Preemption*, page 4-31, for a list of which registers are saved.
3. HWI objects cannot be created dynamically because they correspond to DSP interrupts. However, interrupt functions can be changed at run time.
4. When a HWI function calls HWI_enter, it can pass a bitmask that indicates which interrupts to enable while the HWI function runs. An enabled interrupt can preempt the HWI function even if the enabled interrupt has a lower priority than the current interrupt.
4.1.4 Thread Priorities

Within DSP/BIOS, hardware interrupts have the highest priority. The Configuration Tool lists HWI objects in order from highest to lowest priority as shown in Figure 4-1, but this priority is not maintained implicitly by DSP/BIOS. The priority only applies to the order in which multiple interrupts that are ready on a given CPU cycle are serviced by the CPU. Hardware interrupts are preempted by another interrupt unless that interrupt is disabled by resetting the GIE bit in the CSR, or by setting the corresponding bit in the IER.

Figure 4-1. Thread Priorities

Software interrupts have lower priority than hardware interrupts. There are 14 priority levels available for software interrupts. Software interrupts can be preempted by a higher-priority software interrupt or any hardware interrupt. Software interrupts cannot block.

Tasks have lower priority than software interrupts. There are 15 task priority levels. Tasks can be preempted by any higher-priority thread. Tasks can block while waiting for resource availability and lower-priority threads.

The background idle loop is the thread with the lowest priority of all. It runs in a loop when the CPU is not busy running another thread.
Overview of Thread Scheduling

4.1.5 Yielding and Preemption

The DSP/BIOS schedulers run the highest-priority thread that is ready to run except in the following cases:

- The thread that is running disables some or all hardware interrupts temporarily (with HWI_disable or HWI_enter), preventing hardware ISRs from running.
- The thread that is running disables software interrupts temporarily (with SWI_disable). This prevents any higher-priority software interrupt from preempting the current thread. It does not prevent hardware interrupts from preempting the current thread.
- The thread that is running disables task scheduling temporarily (with TSK_disable). This prevents any higher-priority task from preempting the current task. It does not prevent software and hardware interrupts from preempting the current task.
- The highest-priority thread is a task that is blocked. This occurs if the task calls TSK_sleep, LCK_pend, MBX_pend, or SEM_pend.

Both hardware and software interrupts can interact with the DSP/BIOS task scheduler. When a task is blocked, it is often because the task is pending on a semaphore which is unavailable. Semaphores can be posted from HWIs and SWIs as well as from other tasks. If an HWI or SWI posts a semaphore to unblock a pending task, the processor switches to that task if that task has a higher priority than the currently running task.

When running either an HWI or SWI, DSP/BIOS uses a dedicated system interrupt stack, called the system stack. Each task uses its own private stack. Therefore, if there are no TSK tasks in the system, all threads share the same system stack. Because DSP/BIOS uses separate stacks for each task, both the application and task stacks can be smaller. Because the system stack is smaller, you can place it in precious fast memory.

Table 4-2 shows what happens when one type of thread is running (top row) and another thread becomes ready to run (left column). The results depend on whether or not the type of thread that is ready to run is enabled or disabled. (The action shown is that of the thread that is ready to run.)
Table 4-2.  Thread Preemption

</tr>
</tbody>
</table>

Figure 4-2 shows the execution graph for a scenario in which SWIs and HWIs are enabled (the default), and a hardware interrupt routine posts a software interrupt whose priority is higher than that of the software interrupt running when the interrupt occurs. Also, a second hardware interrupt occurs while the first ISR is running. The second ISR is held off because the first ISR masks off (that is, disables) the second interrupt during the first ISR.
In Figure 4-2, the low priority software interrupt is asynchronously preempted by the hardware interrupts. The first ISR posts a higher-priority software interrupt, which is executed after both hardware interrupt routines finish executing.
4.2 Hardware Interrupts

Hardware interrupts handle critical processing that the application must perform in response to external asynchronous events. The DSP/BIOS HWI module is used to manage hardware interrupts.

In a typical DSP system, hardware interrupts are triggered either by on-device peripherals or by devices external to the DSP. In both cases, the interrupt causes the processor to vector to the ISR address. The address to which a DSP/BIOS HWI object causes an interrupt to vector can be a user routine or the common system HWI dispatcher.

Hardware ISRs can be written using assembly language, C, or a combination of both. HWI functions are usually written in assembly language for efficiency. To allow an HWI object’s function to be written completely in C, the system HWI dispatcher should be used.

All hardware interrupts run to completion. If an HWI is posted multiple times before its ISR has a chance to run, the ISR runs only one time. For this reason, you should minimize the amount of code performed by an HWI function. If the GIE bit is enabled, a hardware interrupt can be preempted by any interrupt that is enabled by the IEMASK.

If an HWI function calls any of the PIP APIs—PIP_alloc, PIP_free, PIP_get, PIP_put—the pipe’s notifyWriter or notifyReader functions run as part of the HWI context.

**Note:**

The *interrupt* keyword or INTERRUPT pragma must not be used when HWI objects are used in conjunction with C functions. The HWI_enter/ HWI_exit macros and the HWI dispatcher contain this functionality, and the use of the C modifier can cause catastrophic results.

4.2.1 Configuring Interrupts with the Configuration Tool

In the DSP/BIOS configuration template, the HWI Manager contains an HWI object for each hardware interrupt in your DSP.

Using the HWI Manager in the Configuration Tool, you can configure the ISR for each hardware interrupt in the DSP.
Hardware Interrupts

You need to enter only the name of the ISR that is called in response to a hardware interrupt in the Property Page of the corresponding HWI object in the Configuration Tool. DSP/BIOS takes care of setting up the interrupt table so that each hardware interrupt is handled by the appropriate ISR. The Configuration Tool also allows you to select the memory segment where the interrupt table is located.

The online help in the Configuration Tool describes HWI objects and their parameters. See HWI Module in the TMS320 DSP/BIOS API Reference Guide for your platform for reference information on the HWI module API calls.

4.2.2 Disabling and Enabling Hardware Interrupts

Within a software interrupt or task, you can temporarily disable hardware interrupts during a critical section of processing. The HWI_disable and HWI_enable/HWI_restore functions are used in pairs to disable and enable interrupts.

When you call HWI_disable, interrupts are globally disabled in your application. On the C6000 platform, HWI_disable clears the GIE bit in the control status register (CSR). On the C5000 platform, HWI_disable sets the INTM bit in the ST1 register. On both platforms, this prevents the CPU from taking any maskable hardware interrupt. Hardware interrupts, therefore, operate on a global basis, affecting all interrupts, as opposed to affecting individual bits in the interrupt enable register. To reenable interrupts, call HWI_enable or HWI_restore. HWI_enable always enables the GIE bit on the C6000 platform or clears the INTM bit in the ST1 register on the C5000 platform, while HWI_restore restores the value to the state that existed before HWI_disable was called.

Figure 4-1 shows two code examples of regions protected from all interrupts.

4-12
Example 4-1. Code Regions That are Uninterruptible

(a) Assembly Code

```assembly
.include hwi.h54
...
HWI_disable A ; disable all interrupts, save the old intm
value in reg A
   "do some critical operation"
HWI_restore A0
```

(b) C Code

```c
.include hwi.h

Uns oldmask;

oldmask = HWI_disable();
   "do some critical operation;"
   "do not call TSK_sleep(), SEM_post, etc."
HWI_restore(oldmask);
```

Using HWI_restore instead of HWI_enable allows the pair of calls to be nested. If the calls are nested, the outermost call to HWI_disable turns interrupts off, and the innermost call to HWI_disable does nothing. Interrupts are not reenabled until the outermost call to HWI_restore. Be careful when using HWI_enable because this call enables interrupts even if they were already disabled when HWI_disable was called.

Note:

DSP/Bios kernel calls that can cause task rescheduling (for example, SEM_post and TSK_sleep) should be avoided within a block surrounded by HWI_disable and HWI_enable since the interrupts can be disabled for an indeterminant amount of time if a task switch occurs.
4.2.3 Context and Interrupt Management within Interrupts

When a hardware interrupt preempts the function that is currently executing, the HWI function must save and restore any registers it uses or modifies. DSP/BIOS provides the HWI_enter assembly macro to save registers and the HWI_exit assembly macro to restore registers. Using these macros gives the function that was preempted the same context when it resumes running. In addition to the register context saving/restoring functionality, the HWI_enter/ HWI_exit macros perform the following system level operations:

- ensure the SWI and TSK schedulers are called at the appropriate times
- disable/restore individual interrupts while the ISR executes

The HWI_enter assembly macro must be called prior to any DSP/BIOS API calls that could post or affect a software interrupt or semaphore. The HWI_exit assembly macro must be called at the very end of the function’s code.

In order to support interrupt routines written completely in C, DSP/BIOS provides an HWI dispatcher that performs these enter and exit macros for an interrupt routine. An HWI can handle context saving and interrupt disabling using this HWI dispatcher or by explicitly calling HWI_enter and HWI_exit. The Configuration Tool allows you to choose whether the HWI dispatcher is used for individual HWI objects. The HWI dispatcher is the preferred method for handling interrupts.

The HWI dispatcher, in effect, calls the configured HWI function from within an HWI_enter/HWI_exit macro pair. This allows the HWI function to be written completely in C. It would, in fact, cause a system crash were the dispatcher to call a function that contains the HWI_enter/HWI_exit macro pair. Using the dispatcher therefore allows for only one instance of the HWI_enter and HWI_exit code.

**Note:**

The `interrupt` keyword or INTERRUPT pragma must not be used when HWI objects are used in conjunction with C functions. The HWI_enter/ HWI_exit macros and the HWI dispatcher contain this functionality, and the use of the C modifier can cause catastrophic results.
Whether called explicitly, C55 or by the HWI dispatcher, the HWI_enter and HWI_exit macros prepare an ISR to call any C function. In particular, the ISR is prepared to call any DSP/BIOS API function that is allowed to be called from the context of an HWI. (See Functions Callable by Tasks, SWI Handlers, or Hardware ISRs in the TMS320 DSP/BIOS API Reference Guide for your platform for a complete list of these functions.)

**Note:**
When using the system HWI dispatcher on the C6000 and C54x platforms, the HWI function must not call HWI_enter and HWI_exit.

Regardless of which HWI dispatching method is used, DSP/BIOS uses the system stack during the execution of both SWIs and HWIs. If there are no TSK tasks in the system, this system stack is used by all threads. If there are TSK tasks, each task uses its own private stack. Whenever a task is preempted by an SWI or HWI, DSP/BIOS uses the system stack for the duration of the interrupt thread.

HWI_enter and HWI_exit both take two parameters on the C54x platform:

- The first, **MASK**, specifies which CPU registers are to be saved and restored by the ISR.
- The second parameter of HWI_enter and HWI_exit on the C54x platform, **IMRDISABLEMASK**, is a mask of those interrupts that are to be disabled between the HWI_enter and HWI_exit macro calls.

When an interrupt is triggered, the processor disables interrupts globally (by setting the INTM bit in the status register ST1) and then jumps to the ISR set up in the interrupt vector table. The HWI_enter macro reenables interrupts by clearing the INTM bit in the ST1 register. Before doing so, HWI_enter selectively disables some interrupts by clearing the appropriate bits in the interrupt mask register (IMR). The bits that are cleared in the IMR are determined by the IMRDISABLEMASK input parameter passed to the HWI_enter macro. Hence, HWI_enter gives you control to select what interrupts can and cannot preempt the current HWI function.
When HWI\_exit is called, you can also provide an IMRRESTOREMASK parameter. The bit pattern in the IMRRESTOREMASK determines what interrupts are restored by HWI\_exit, by setting the corresponding bits in the IMR. Of the interrupts in IMRRESTOREMASK, HWI\_exit restores only those that were disabled with HWI\_enter. If upon exiting the ISR you do not wish to restore one of the interrupts that was disabled with HWI\_enter, do not set that interrupt bit in IMRRESTOREMASK in HWI\_exit. HWI\_exit does not affect the status of interrupt bits that are not in IMRRESTOREMASK.

The C55x platform can have seven parameters in all, the first five specify which CPU registers to save as context, and the last two can specify two interrupt mask bitmaps.

HWI\_enter and HWI\_exit both take four parameters on the C6000 platform:

- The first two, ABMASK and CMASK, specify which A, B, and control registers are to be saved and restored by the ISR.
- The third parameter on the C6000 platform, IEMASK, is a mask of those interrupts that are to be disabled between the HWI\_enter and HWI\_exit macro calls.

When an interrupt is triggered, the processor disables interrupts globally (by clearing the GIE bit in the control status register (CSR)) and then jumps to the ISR set up in the interrupt service table. The HWI\_enter macro reenables interrupts by setting the GIE in the CSR. Before doing so, HWI\_enter selectively disables bits in the interrupt enable register (IER) determined by the IEMASK parameter. Hence, HWI\_enter gives you control to select what interrupts can and cannot preempt the current HWI function.

When HWI\_exit is called, the bit pattern in the IEMASK determines what interrupts are restored by HWI\_exit by setting the corresponding bits in the IER. Of the interrupts in IEMASK, HWI\_exit restores only those that were disabled with HWI\_enter. If upon exiting the ISR you do not want to restore one of the interrupts that was disabled with HWI\_enter, do not set that interrupt bit in IEMASK in HWI\_exit. HWI\_exit does not affect the status of interrupt bits that are not in IEMASK.
The fourth parameter on the C6000 platform, CCMASK, specifies the value to place in the cache control field of the CSR. This cache state remains in effect for the duration of code executed between the HWI_enter and HWI_exit calls. Some typical values for this mask are defined in c62.h62 (for example, C62_PCC_ENABLE). You can OR the PCC code and DCC code together to generate CCMASK. If you use 0 as CCMASK, a default value is used. You set this value in the Global Settings Properties in the Configuration Tool by right-clicking and selecting Properties.

CLK_F_isr, which handles one of the on-device timer interrupts when the Clock Manager is enabled, also uses the default cache value set by the Configuration Tool. HWI_enter saves the current CSR status before it sets the cache bits as defined by CCMASK. HWI_exit restores CSR to its value at the interrupted context.

The predefined masks C62_ABTEMPS and C62_CTEMPS (C62x) or C64_ABTEMPS and C64_CTEMPS (C64x) specify all of the C language temporary A/B registers and all of the temporary control registers, respectively. These masks can be used to save the registers that can be freely used by a C function. When using the HWI dispatcher on the C6000 platform, there is no ability to specify a register set, so the registers specified by these masks are all saved and restored.

For example, if your HWI function calls a C function you would use:

```
HWI_enter C62_ABTEMPS, C62_CTEMPS, IEMASK, CCMASK
   'isr code'
HWI_exit C62_ABTEMPS, C62_CTEMPS, IEMASK, CCMASK
```

HWI_enter should be used to save all of the C run-time environment registers before calling any C or DSP/BIOS functions. HWI_exit should be used to restore these registers.

In addition to saving and restoring the C run-time environment registers, HWI_enter and HWI_exit make sure the DSP/BIOS scheduler is called only by the outermost interrupt routine if nested interrupts occur. If the HWI or another nested HWI triggers an SWI handler with SWI_post, or readies a higher priority task (for example, by calling SEM_ipost or TSK_itick), the outermost HWI_exit invokes the SWI and TSK schedulers. The SWI scheduler services all pending SWI handlers before performing a context switch to a higher priority task (if necessary).

See Functions Callable by Tasks, SWI Handlers, or Hardware ISRs in the TMS320 DSP/BIOS API Reference Guide for your platform for a complete list of functions that can be called by an ISR.
Note:

HWI_enter and HWI_exit must surround all statements in any DSP/BIOS assembly or C language HWIs that reference DSP/BIOS functions. Using the HWI dispatcher satisfies this requirement.

Example 4-2 provides assembly language code for constructing a minimal HWI on the C6000 platform when the user has selected not to use the HWI dispatcher. Example 4-3 provides a code example on the C54x platform and an example on the C55x is shown in Example 4-4. These examples use HWI_enter and give you more precise control.

Example 4-2. Constructing a Minimal ISR on C6000 Platform.

```assembly
; ======== myclk.s62 ========
.include "hwi.h62" ; macro header file
IEMASK .set 0
CCMASK .set c62_PCC_DISABLE
.text

; ======== myclkisr ========
.global _myclkisr
_myclkisr:

; save all C run-time environment registers
HWI_enter C62_ABTEMPS, C62_CTEMPS, IEMASK, CCMASK

b _TSK_itick ; call TSK_itick (C function)
mvkl tiret, b3
mvkh tiret, b3
nop 3

; restore saved registers and call DSP/BIOS scheduler
HWI_exit C62_ABTEMPS, C62_CTEMPS, IEMASK, CCMASK

.end
```
Example 4-3. HWI Example on C54x Platform

```c
; ======== _DSS_isr ========
; Calls the C ISR code after setting cpl
; and saving C54_CNOTPRESERVED
;
.include "hwi.h54" ; macro header file

_DSS_isr:
    HWI_enter    C54_CNOTPRESERVED, 0fff7h
    ; cpl = 0
    ; dp = GBL_A_SYSPAGE
    ; We need to set cpl bit when going to C
    ssbx    cpl
    nop        ; cpl latency
    nop        ; cpl latency
    call    _DSS_cisr
    rsbx    cpl            ; HWI_exit precondition
    nop        ; cpl latency
    nop        ; cpl latency
    ld    #GBL_A_SYSPAGE, dp
    HWI_exit    C54_CNOTPRESERVED, 0fff7h
```

Example 4-4. HWI Example on C55x Platform

```c
; ======== _DSS_isr ========

_DSS_isr:
    HWI_enter C55_AR_DR_SAVE_BY_CALLER_MASK,
                C55_ACC_SAVE_BY_CALLER_MASK,
                C55_MISC1_SAVE_BY_CALLER_MASK,
                C55_MISC2_SAVE_BY_CALLER_MASK,
                C55_MISC3_SAVE_BY_CALLER_MASK,
                0FFF7h,0
    ; macro has ensured ‘C’ convention,
    ; including SP alignment!
    call    _DSS_cisr
    HWI_exit C55_AR_DR_SAVE_BY_CALLER_MASK,
              C55_ACC_SAVE_BY_CALLER_MASK,
              C55_MISC1_SAVE_BY_CALLER_MASK,
              C55_MISC2_SAVE_BY_CALLER_MASK,
              C55_MISC3_SAVE_BY_CALLER_MASK,
              0FFF7h,0
```

4.2.4 Registers

DSP/BIOS registers saved and restored with C functions conform to standard C compiler code. For more information, either about which registers are saved and restored, or by the TMS320 functions conforming to the Texas Instruments C run-time model, see the optimizing compiler user’s guide for your platform.
4.3 Software Interrupts

Software interrupts are patterned after hardware ISRs. The SWI module in DSP/BIOS provides a software interrupt capability. Software interrupts are triggered programmatically, through a call to a DSP/BIOS API such as SWI_post. Software interrupts have priorities that are higher than tasks but lower than hardware interrupts.

The SWI module should not be confused with the SWI instruction that exists on many processors. The DSP/BIOS SWI module is independent from any processor-specific software interrupt features.

SWI threads are suitable for handling application tasks that occur at slower rates or are subject to less severe real-time deadlines than those of hardware interrupts.

The DSP/BIOS APIs that can trigger or post a software interrupt are:
- SWI_andn
- SWI_dec
- SWI_inc
- SWI_or
- SWI_post

The SWI Manager controls the execution of all software interrupts. When the application calls one of the APIs above, the SWI Manager schedules the function corresponding to the software interrupt for execution. To handle all software interrupts in an application, the SWI Manager uses SWI objects.

If a software interrupt is posted, it runs only after all pending hardware interrupts have run. An SWI routine in progress can be preempted at any time by an HWI; the HWI completes before the SWI handler resumes. On the other hand, SWI handlers always preempt tasks. All pending software interrupts run before even the highest priority task is allowed to run. In effect, an SWI handler is like a task with a priority higher than all ordinary tasks.

Note:
Two things to remember about SWI are:

An SWI handler runs to completion unless it is interrupted by a hardware interrupt or preempted by a higher priority SWI.

When called within an HWI ISR, the code sequence calling any of the SWI functions which can trigger or post a software interrupt must be either wrapped within an HWI_enter/HWI_exit pair or invoked by the HWI dispatcher.
4.3.1 Creating SWI Objects

As with many other DSP/BIOS objects, you can create SWI objects either dynamically (with a call to SWI_create) or statically (with the Configuration Tool). Software interrupts you create dynamically can also be deleted during program execution.

To add a new software interrupt with the Configuration Tool, create a new SWI object for the SWI Manager in the Configuration Tool. In the Property Page of each SWI object, you can set the function each software interrupt is to run when the object is triggered by the application. The Configuration Tool also allows you to enter two arguments for each SWI function.

In the Property Page of the SWI Manager, you can determine from which memory segment SWI objects are allocated. SWI objects are accessed by the SWI Manager when software interrupts are posted and scheduled for execution.

The online help in the Configuration Tool describes SWI objects and their parameters. See SWI Module in the TMS320 DSP/BIOS API Reference Guide for your platform for reference information on the SWI module API calls.

To create a software interrupt dynamically, use a call with this syntax:

swi = SWI_create(attrs);

Here, swi is the interrupt handle and the variable attrs points to the SWI attributes. The SWI attribute structure (of type SWI_Attrs) contains all those elements that can be configured for an SWI using the Configuration Tool. attrs can be NULL, in which case, a default set of attributes is used. Typically, attrs contains at least a function for the handler.

**Note:**

SWI_create can only be called from the task level, not from an HWI or another SWI.

SWI_getattrs can be used to retrieve all the SWI_Attrs attributes. Some of these attributes can change during program execution, but typically they contain the values assigned when the object was created.

SWI_getattrs(swi, attrs);
4.3.2 Setting Software Interrupt Priorities in the Configuration Tool

There are different priority levels among software interrupts. You can create as many software interrupts as your memory constraints allow for each priority level. You can choose a higher priority for a software interrupt that handles a thread with a shorter real-time deadline, and a lower priority for a software interrupt that handles a thread with a less critical execution deadline.

To set software interrupt priorities with the Configuration Tool, follow these steps:

1) In the Configuration Tool, highlight the Software Interrupt Manager. Notice SWI objects in the right half of the window shown in Figure 4-3. They are organized by priority in priority level folders. (If you do not see a list of SWI objects in the right half of the window, right-click on the SWI Manager, then choose View→Ordered collection view.)

Figure 4-3. Software Interrupt Manager
2) To change the priority of a SWI object, drag the software interrupt to the folder of the corresponding priority. For example, to change the priority of SWI0 to 3, select it with the mouse and drag it to the folder labeled Priority 3.

Software interrupts can have up to 15 priority levels. The highest level is SWI_MAXPRI (14). The lowest is SWI_MINPRI (0). The priority level of 0 is reserved for the KNL_swi object, which runs the task scheduler. See section 4.3.3, Software Interrupt Priorities and Application Stack Size, page 4-23, for stack size restrictions. You cannot sort software interrupts within a single priority level.

The Property window for an SWI object shows its numeric priority level (from 0 to 14; 14 is the highest level). You can also set the priority by selecting the priority level from the menu in the Property window as shown in Figure 4-4.

Figure 4-4. SWI Properties Dialog Box

4.3.3 Software Interrupt Priorities and Application Stack Size

All threads in DSP/BIOS, excluding tasks, are executed using the same system stack.

The system stack stores the register context when a software interrupt preempts another thread. To allow the maximum number of preemptions that can occur at run time, the required stack size grows each time you add a software interrupt priority level. Thus, giving software interrupts the same priority level is more efficient in terms of stack size than giving each software interrupt a separate priority.

The default system stack size for the MEM module is 256 words. You can change the sizes in the Configuration Tool. The estimated sizes required are shown in the status bar at the top of the Configuration Tool.
You can have up to 15 software interrupt priority levels, but each level requires a larger system stack. If you see a pop-up message that says “the system stack size is too small to support a new software interrupt priority level,” increase the Application Stack Size property of the Memory Section Manager.

Creating the first PRD object creates a new SWI object called PRD_swi (see section 4.9, Periodic Function Manager (PRD) and the System Clock, page 4-68, for more information on PRD). If no SWI objects have been created before the first PRD object is added, adding PRD_swi uses the first priority level, producing a corresponding increase in the required system stack.

If the TSK Manager has been enabled, the TSK scheduler (run by an SWI object named KNL_swi) reserves the lowest SWI priority level. No other SWI objects can have that priority.

4.3.4 Execution of Software Interrupts

Software interrupts can be scheduled for execution with a call to SWI_andn, SWI_dec, SWI_inc, SWI_or, and SWI_post. These calls can be used virtually anywhere in the program—interrupt service routines, periodic functions, idle functions, or other software interrupt functions.

When an SWI object is posted, the SWI Manager adds it to a list of posted software interrupts that are pending execution. Then the SWI Manager checks whether software interrupts are currently enabled. If they are not, as is the case inside an HWI function, the SWI Manager returns control to the current thread.

If software interrupts are enabled, the SWI Manager checks the priority of the posted SWI object against the priority of the thread that is currently running. If the thread currently running is the background idle loop or a lower priority SWI, the SWI Manager removes the SWI from the list of posted SWI objects and switches the CPU control from the current thread to start execution of the posted SWI function.

If the thread currently running is an SWI of the same or higher priority, the SWI Manager returns control to the current thread, and the posted SWI function runs after all other SWIs of higher priority or the same priority that were previously posted finish execution.
Software Interrupts

Note:

Two things to remember about SWI:

When an SWI starts executing it must run to completion without blocking.

When called from within an HWI, the code sequence calling any of the SWI functions which can trigger or post a software interrupt must be either wrapped within an HWI_enter/HWI_exit pair or invoked by the HWI dispatcher.

SWI functions can be preempted by threads of higher priority (such as an HWI or an SWI of higher priority). However, SWI functions cannot block. You cannot suspend a software interrupt while it waits for something—like a device—to be ready.

If an SWI is posted multiple times before the SWI Manager has removed it from the posted SWI list, its SWI function executes only once, much like an HWI is executed only once if the hardware interrupt is triggered multiple times before the CPU clears the corresponding interrupt flag bit in the interrupt flag register. (See section 4.3.5, Using an SWI Object’s Mailbox, page 4-25, for more information on how to handle SWIs that are posted multiple times before they are scheduled for execution.)

Applications should not make any assumptions about the order in which SWI handlers of equal priority are called. However, an SWI handler can safely post itself (or be posted by another interrupt). If more than one is pending, all SWI handlers are called before any tasks run.

4.3.5 Using an SWI Object’s Mailbox

Each SWI object has a 32-bit mailbox for C6000 and a 16-bit mailbox for C5400, which are used either to determine whether to post the software interrupt or as values that can be evaluated within the SWI function.

SWI_post, SWI_or, and SWI_inc post an SWI object unconditionally:

- SWI_post does not modify the value of the SWI object mailbox when it is used to post a software interrupt.
- SWI_or sets the bits in the mailbox determined by a mask that is passed as a parameter, and then posts the software interrupt.
- SWI_inc increases the SWI’s mailbox value by one before posting the SWI object.
SWI\_andn and SWI\_dec post the SWI object only if the value of its mailbox becomes 0:

- SWI\_andn clears the bits in the mailbox determined by a mask passed as a parameter.
- SWI\_dec decreases the value of the mailbox by one.

Table 4-3 summarizes the differences between these functions.

**Table 4-3. SWI Object Function Differences**

<table>
<thead>
<tr>
<th>Action</th>
<th>Treats Mailbox as Bitmask</th>
<th>Treats Mailbox as Counter</th>
<th>Does not Modify Mailbox</th>
</tr>
</thead>
<tbody>
<tr>
<td>Always post</td>
<td>SWI_or</td>
<td>SWI_inc</td>
<td>SWI_post</td>
</tr>
<tr>
<td>Post if it becomes zero</td>
<td>SWI_andn</td>
<td>SWI_dec</td>
<td>—</td>
</tr>
</tbody>
</table>

The SWI mailbox allows you to have tighter control over the conditions that should cause an SWI function to be posted, or the number of times the SWI function should be executed once the software interrupt is posted and scheduled for execution.

To access the value of its mailbox, an SWI function can call SWI\_getmbox. SWI\_getmbox can be called only from the SWI's object function. The value returned by SWI\_getmbox is the value of the mailbox before the SWI object was removed from the posted SWI queue and the SWI function was scheduled for execution.

When the SWI Manager removes a pending SWI object from the posted object's queue, its mailbox is reset to its initial value. The initial value of the mailbox is set from the Property Page when the SWI object is created with the Configuration Tool. If while the SWI function is executing it is posted again, its mailbox is updated accordingly. However, this does not affect the value returned by SWI\_getmbox while the SWI functions execute. That is, the mailbox value that SWI\_getmbox returns is the latched mailbox value when the software interrupt was removed from the list of pending SWIs. The SWI's mailbox however, is immediately reset after the SWI is removed from the list of pending SWIs and scheduled for execution. This gives the application the ability to keep updating the value of the SWI mailbox if a new posting occurs, even if the SWI function has not finished its execution.

For example, if an SWI object is posted multiple times before it is removed from the queue of posted SWIs, the SWI Manager schedules its function to execute only once. However, if an SWI function must always run multiple times when the SWI object is posted multiple times, SWI\_inc should be used to post the SWI as shown in Figure 4-5.
When an SWI has been posted using SWI_inc, once the SWI Manager calls the corresponding SWI function for execution, the SWI function can access the SWI object mailbox to know how many times it was posted before it was scheduled to run, and proceed to execute the same routine as many times as the value of the mailbox.

**Figure 4-5. Using SWI_inc to Post an SWI**

```c
myswiFxn()
{
    . . .
    repetitions = SWI_getmbox();
    while (repetitions -->)
    {
        “run SWI routine"
    }
    . . .
}
```
If more than one event must always happen for a given software interrupt to be triggered, SWI_andn should be used to post the corresponding SWI object as shown in Figure 4-6. For example, if a software interrupt must wait for input data from two different devices before it can proceed, its mailbox should have two set bits when the SWI object was created with the Configuration Tool. When both routines that provide input data have completed their tasks, they should both call SWI_andn with complementary bitmasks that clear each of the bits set in the SWI mailbox default value. Hence, the software interrupt is posted only when data from both processes is ready.

Figure 4-6. Using SWI_andn to Post an SWI

In some situations the SWI function can call different routines depending on the event that posted it. In that case the program can use SWI_or to post the SWI object unconditionally when an event happens. This is shown in Figure 4-7. The value of the bitmask used by SWI_or encodes the event type that triggered the post operation, and can be used by the SWI function as a flag that identifies the event and serves to choose the routine to execute.
If the program execution requires that multiple occurrences of the same event must take place before an SWI is posted, SWI_decay should be used to post the SWI as shown in Figure 4-8. By configuring the SWI mailbox to be equal to the number of occurrences of the event before the SWI should be posted and calling SWI_decay every time the event occurs, the SWI is posted only after its mailbox reaches 0; that is, after the event has occurred a number of times equal to the mailbox value.
**4.3.6 Benefits and Tradeoffs**

There are two main benefits to using software interrupts instead of hardware interrupts.

First, SWI handlers can execute with all hardware interrupts enabled. To understand this advantage, recall that a typical HWI modifies a data structure that is also accessed by tasks. Tasks therefore need to disable hardware interrupts when they wish to access these data structures in a mutually exclusive way. Obviously, disabling hardware interrupts always has the potential to degrade the performance of a real-time system.

Conversely, if a shared data structure is modified by an SWI handler instead of an HWI, mutual exclusion can be achieved by disabling software interrupts while the task accesses the shared data structure (SWI_disable and SWI_enable are described later in this chapter). Thus, there is no effect on the ability of the system to respond to events in real-time using hardware interrupts.

It often makes sense to break long ISRs into two pieces. The HWI takes care of the extremely time-critical operation and defers the less critical processing to an SWI handler.
The second advantage is that an SWI handler can call some functions that cannot be called from an HWI, because an SWI handler is guaranteed not to run while DSP/BIOS is updating internal data structures. This is an important feature of DSP/BIOS and you should become familiar with the table, *Functions Callable by Tasks, SWI Handlers, or Hardware ISRs* in the *TMS320 DSP/BIOS API Reference Guide* for your platform that lists DSP/BIOS functions and the threads from which each function can be called.

**Note:**
SWI handlers can call any DSP/BIOS function that does not block. For example, SEM_pend can make a task block, so SWI handlers cannot call SEM_pend or any function that calls SEM_pend (for example, MEM_alloc, TSK_sleep).

On the other hand, an SWI handler must complete before any blocked task is allowed to run. There might be situations where the use of a task might fit better with the overall system design, in spite of any additional overhead involved.

### 4.3.7 Saving Registers During Software Interrupt Preemption

When a software interrupt preempts another thread, DSP/BIOS preserves the context of the preempted thread by automatically saving all of the CPU registers shown in Table 4-4 onto the system stack.

</table>

Your SWI function does not need to save and restore any of these registers, even if the SWI function is written in assembly.
However, SWI functions that are written in assembly must follow C register usage conventions. For the C6000 platform, they must save and restore any of the registers numbered A10 to A15 and B10 to B15. On the C5000 platform, they must save and restore registers ar1, ar6, and ar7. (See the optimizing compiler user’s guide for your platform for more details on C register conventions.)

An SWI function that modifies the IER register should save it and then restore it before it returns. If the SWI function fails to do this, the change becomes permanent and any other thread that starts to run or that the program returns to afterwards can inherit the modification to the IER.

The context is not saved automatically within an HWI function. You must use the HWI_enter and HWI_exit macros or the HWI dispatcher to preserve the interrupted context when an HWI function is triggered.

4.3.8 Synchronizing SWI Handlers

Within an idle loop function, task, or software interrupt function, you can temporarily prevent preemption by a higher-priority software interrupt by calling SWI_disable, which disables all SWI preemption. To reenable SWI preemption, call SWI_enable.

Software interrupts are enabled or disabled as a group. An individual software interrupt cannot be enabled or disabled on its own.

When DSP/BIOS finishes initialization and before the first task is called, software interrupts have been enabled. If an application wishes to disable software interrupts, it calls SWI_disable as follows:

```c
key = SWI_disable();
```

The corresponding enable function is SWI_enable.

```c
SWI_enable(key);
```

key is a value used by the SWI module to determine if SWI_disable has been called more than once. This allows nesting of SWI_disable / SWI_enable calls, since only the outermost SWI_enable call actually enables software interrupts. In other words, a task can disable and enable software interrupts without having to determine if SWI_disable has already been called elsewhere.

When software interrupts are disabled, a posted software interrupt does not run at that time. The interrupt is “latched” in software and runs when software interrupts are enabled and it is the highest-priority thread that is ready to run.
**Note:**

An important side effect of SWI_disable is that task preemption is also disabled. This is because DSP/BIOS uses software interrupts internally to manage semaphores and clock ticks.

To delete a dynamically created software interrupt, use SWI_delete.

The memory associated with swi is freed. SWI_delete can only be called from the task level.
4.4 Tasks

DSP/BIOS task objects are threads that are managed by the TSK module. Tasks have higher priority than the idle loop and lower priority than hardware and software interrupts.

The TSK module dynamically schedules and preempts tasks based on the task’s priority level and the task’s current execution state. This ensures that the processor is always given to the highest priority thread that is ready to run. There are 15 priority levels available for tasks. The lowest priority level (0) is reserved for running the idle loop.

The TSK module provides a set of functions that manipulate task objects. They access TSK object through handles of type TSK_Handle.

The kernel maintains a copy of the processor registers for each task object. Each task has its own run-time stack for storing local variables as well as for further nesting of function calls.

Stack size can be specified separately for each TSK object. Each stack must be large enough to handle normal subroutine calls as well as a single task preemption context. A task preemption context is the context that gets saved when one task preempts another as a result of an interrupt thread readying a higher priority task. If the task blocks, only those registers that a C function must save are saved to the task stack. To find the correct stack size, you can make the stack size large and then use Code Composer Studio software to find the stack size actually used.

All tasks executing within a single program share a common set of global variables, accessed according to the standard rules of scope defined for C functions.

4.4.1 Creating Tasks

You can create TSK objects either dynamically (with a call to TSK_create) or statically (with the Configuration Tool). Tasks that you create dynamically can also be deleted during program execution.
4.4.1.1 Creating and Deleting Tasks Dynamically

You can spawn DSP/BIOS tasks by calling the function TSK_create, whose parameters include the address of a C function in which the new task begins its execution. The value returned by TSK_create is a handle of type TSK_Handle, which you can then pass as an argument to other TSK functions.

```c
TSK_Handle TSK_create(fxn, attrs, [arg,] ...)
  Fxn    fxn;
  TSK_Attrs  *attrs
  Arg       arg
```

A task becomes active when it is created and preempts the currently running task if it has a higher priority.

The memory used by TSK objects and stacks can be reclaimed by calling TSK_delete. TSK_delete removes the task from all internal queues and frees the task object and stack by calling MEM_free.

Any semaphores, mailboxes, or other resources held by the task are not released. Deleting a task that holds such resources is often an application design error, although not necessarily so. In most cases, such resources should be released prior to deleting the task.

```c
Void TSK_delete(task)
  TSK_Handle    task;
```

**Note:**

Catastrophic failure can occur if you delete a task that owns resources that are needed by other tasks in the system. See TSK_delete, in the TMS320 DSP/BIOS API Reference Guide for your platform for details.
4.4.1.2 Creating Tasks with the Configuration Tool

You can also create tasks using the Configuration Tool. The Configuration Tool allows you to set a number of properties for each task and for the TSK Manager itself.

While it is running, a task that was created with the Configuration Tool behaves exactly the same as a task created with TSK_create. You cannot use the TSK_delete function to delete tasks created with the Configuration Tool. See section 2.2.4, Creating Objects Using the Configuration Tool, page 2-4, for a discussion of the benefits of creating objects with the Configuration Tool.

The default configuration template defines the TSK_idle task which must have the lowest priority. It runs the functions defined for the IDL objects when no higher-priority task or interrupt is ready.

4.4.1.3 Setting Task Properties in the Configuration Tool

You can view the default TSK properties by clicking on the TSK Manager. Some of these properties include default task priority, stack size, and stack segment. Each time a new TSK object is inserted, its priority, stack size, and stack segment are set to the defaults. You can also set these properties individually for each TSK object. For a complete description of all TSK properties, see TSK Module in the TMS320 DSP/BIOS API Reference Guide for your platform.

To change the priority of a task:

1) Open the TSK module in the Configuration Tool to view all statically created tasks.

2) If you select any task, you see its priority in the list of properties on the right side of the window as shown in Figure 4-9.

Note:

DSP/BIOS splits the specified stack space equally between user (data) stack memory and system stack memory.
3) To change the priority of a task object, drag the task to the folder of the corresponding priority. For example, to change the priority of TSK1 to 3, select it with the mouse and drag it to the folder labeled Priority 3.

4) You can also change the priority of a task in the Properties window which you can select when you right-click on the TSK object pop-up menu.

When you use the Configuration Tool to create tasks of equal priority, they are scheduled in the order in which they are listed in the Configuration Tool window. Tasks can have up to 16 priority levels. The highest level is 15 and the lowest is 0. The priority level of 0 is reserved for the system idle task. You cannot sort tasks within a single priority level.

If you want a task to be created in the suspended mode (TSK_BLOCKED), drag it to the folder labeled Priority -1. For more information on task suspend, see Figure 4-10.

The Property window for a TSK object shows its numeric priority level (from 0 to 15; 15 is the highest level). You can also set the priority by selecting the priority level from the menu in the Property window as shown in Figure 4-10.
4.4.2 Task Execution States and Scheduling

Each TSK task object is always in one of four possible states of execution:

1) **Running**, which means the task is the one actually executing on the system's processor;

2) **Ready**, which means the task is scheduled for execution subject to processor availability;

3) **Blocked**, which means the task cannot execute until a particular event occurs within the system; or

4) **Terminated**, which means the task is “terminated” and does not execute again.

Tasks are scheduled for execution according to a priority level assigned to the application. There can be no more than one running task. As a rule, no ready task has a priority level greater than that of the currently running task, since TSK preempts the running task in favor of the higher-priority ready task.
Unlike many time-sharing operating systems that give each task its “fair share” of the processor, DSP/BIOS immediately preempts the current task whenever a task of higher priority becomes ready to run.

The maximum priority level is TSK_MAXPRI (15); the minimum priority is TSK_MINPRI (1). If the priority is less than 0, the task is barred from further execution until its priority is raised at a later time by another task. If the priority equals TSK_MAXPRI, the task execution effectively locks out all other program activity except for the handling of hardware interrupts and software interrupts.

During the course of a program, each task’s mode of execution can change for a number of reasons. Figure 4-11 shows how execution modes change.

Figure 4-11. Execution Mode Variations

Functions in the TSK, SEM, and SIO modules alter the execution state of task objects: blocking or terminating the currently running task, readying a previously suspended task, re-scheduling the current task, and so forth.

There is one task whose execution mode is TSK_RUNNING. If all program tasks are blocked and no hardware or software interrupt is running, TSK executes the TSK_idle task, whose priority is lower than all other tasks in the system. When a task is preempted by a software or hardware interrupt, the task execution mode returned for that task by TSK_stat is still TSK_RUNNING because the task will run when the preemption ends.
Note:

Do not make blocking calls, such as SEM_pend or TSK_sleep, from within an IDL function. Doing so prevents DSP/BIOS Analysis Tools from gathering run-time information.

When the TSK_RUNNING task transitions to any of the other three states, control switches to the highest-priority task that is ready to run (that is, whose mode is TSK_READY). A TSK_RUNNING task transitions to one of the other modes in the following ways:

- The running task becomes TSK_TERMINATED by calling TSK_exit, which is automatically called if and when a task returns from its top-level function. After all tasks have returned, the TSK Manager terminates program execution by calling SYS_exit with a status code of 0.

- The running task becomes TSK_BLOCKED when it calls a function (for example, SEM_pend or TSK_sleep) that causes the current task to suspend its execution; tasks can move into this state when they are performing certain I/O operations, awaiting availability of some shared resource, or idling.

- The running task becomes TSK_READY and is preempted whenever some other, higher-priority task becomes ready to run. TSK_setpri can cause this type of transition if the priority of the current task is no longer the highest in the system. A task can also use TSK_yield to yield to other tasks with the same priority. A task that yields becomes ready to run.

A task that is currently TSK_BLOCKED transitions to the ready state in response to a particular event: completion of an I/O operation, availability of a shared resource, the elapse of a specified period of time, and so forth. By virtue of becoming TSK_READY, this task is scheduled for execution according to its priority level; and, of course, this task immediately transitions to the running state if its priority is higher than the currently executing task. TSK schedules tasks of equal priority on a first-come, first-served basis.

4.4.3 Testing for Stack Overflow

When a task uses more memory than its stack has been allocated, it can write into an area of memory used by another task or data. This results in unpredictable and potentially fatal consequences. Therefore, a means of checking for stack overflow is useful.
Two functions, TSK_checkstacks, and TSK_stat, can be used to watch stack size. The structure returned by TSK_stat contains both the size of its stack and the maximum number of MADUs ever used on its stack, so this code segment could be used to warn of a nearly full stack:

```c
TSK_Stat statbuf;               /* declare buffer */

TSK_stat(TSK_self(), &statbuf); /* call func to get status */
if (statbuf.used > (statbuf.attrs.stacksize * 9 / 10)) {
    LOG_printf(&trace, "Over 90% of task’s stack is in use.\n")
}
```

See the TSK_stat and TSK_checkstacks sections in the TMS320 DSP/BIOS API Reference Guide for your platform, for a description and examples of their use.

### 4.4.4 Task Hooks

System-specific functions can be called for each task create (TSK_create), task delete (TSK_delete), task exit (TSK_exit), or context switch (TSK_sleep, SEM_pend, etc.). These functions can be used to extend a task’s context beyond the basic processor register set. The user-definable Create function, Delete function, Ready function, and Exit function configuration properties are described in the reference section for the TSK module in the TMS320 DSP/BIOS API Reference Guide for your platform.

The Switch function is invoked during a task switch, if it is not set to the no-operation function, _SYS_nop. Within this function, the application can access both the current and next task handles. For example:

```c
Void (* Switch_function)(TSK_Handle curTask, TSK_Handle nexTask);
```

In this example, the function can be used to save or restore additional task context (for example, external hardware registers), to check for task stack overflow, or to monitor the time used by each task.

The function specified as the Switch function is called from within the kernel and can make only those function calls allowed from within a software interrupt handler (SWI handler). See Functions Callable by Tasks, SWI Handlers, or Hardware ISRs in the TMS320 DSP/BIOS API Reference Guide for your platform for a list of functions callable from an SWI handler.
The function specified as the Ready function is performed when a task becomes ready to run, even though the task might not be allowed to run until other tasks of equal or higher priority block, finish, or yield. This function might be used to examine the scheduling and execution of tasks. Like the Switch function, the Ready function is called from within the kernel and can only call functions allowed within a software interrupt handler (SWI handler).

There are no real constraints on what functions can be called within the Create function, Delete function, and Exit function since these are invoked outside the kernel.

You can set the task hook functions with the Configuration Tool by right-clicking on the TSK Manager and selecting Properties from the pop-up menu. Functions written in C must have the leading underscore (_).

### 4.4.5 Task Hooks for Extra Context

Consider, for example, a system that has special hardware registers (say, for extended addressing) that need to be preserved on a per task basis. In Example 4-5 the function doCreate is used to allocate a buffer to maintain these registers on a per task basis, doDelete is used to free this buffer, and doSwitch is used to save and restore these registers.

If task objects are created with the Configuration Tool, the Switch function should not assume (as Example 4-5 does) that a task’s environment is always set by the Create function.
Example 4-5. Creating a Task Object

```c
#define CONTEXTSIZE `size of additional context`

Void doCreate(task)
    TSK_Handle       task;
{    
    Ptr              context;
    
    context = MEM_alloc(0, CONTEXTSIZE, 0);
    TSK_setenv(task, context); /* set task environment */
}

Void doDelete(task)
    TSK_Handle       task;
{    
    Ptr              context;
    
    context = TSK_getenv(task); /* get register buffer */
    MEM_free(0, context, CONTEXTSIZE);
}

Void doSwitch(from, to)
    TSK_Handle       from;
    TSK_Handle       to;
{    
    Ptr              context;
    static Int first = TRUE;
    if (first) {
        first = FALSE;
        return;
    }
    
    context = TSK_getenv(from); /* get register buffer */
    *context = `hardware registers'; /* save registers */
    
    context = TSK_getenv(to); /* get register buffer */
    `hardware registers' = *context; /* restore registers */
}

Void doExit(Void)
{    
    TSK_Handle    usrHandle;
    /* get task handle, if needed */
    usrHandle = TSK_self();
    
    'perform user-defined exit steps'
}
```

Note:

Non-pointer type function arguments to LOG_printf need explicit type casting to (Arg) as shown in the following code example:

LOG_printf(&trace, "Task %d Done", (Arg)id);
4.4.6 Task Yielding for Time-Slice Scheduling

Example 4-6 demonstrates an implementation of a time-slicing scheduling model that can be managed by a user. This model is preemptive and does not require any cooperation (which is, code) by the tasks. The tasks are programmed as if they were the only thread running. Although DSP/BIOS tasks of differing priorities can exist in any given application, the time-slicing model only applies to tasks of equal priority. Figure 4-12 shows the trace window resulting from Example 4-6, while Figure 4-13 shows the execution graph.

Example 4-6. Time-Slice Scheduling

```c
/*
* ======== slice.c ========
* This example utilizes time-slice scheduling among three
* tasks of equal priority. A fourth task of higher
* priority periodically preempts execution.
* 
* A PRD object drives the time-slice scheduling. Every
* millisecond, the PRD object calls TSK_yield()
* which forces the current task to relinquish access to
* to the CPU. The time slicing could also be driven by
* a CLK object (as long as the time slice was the same interval
* as the clock interrupt), or by another hardware
* interrupt.
* 
* The time-slice scheduling is best viewed in the Execution
* Graph with SWI logging and PRD logging turned off.
* 
* Because a task is always ready to run, this program
* does not spend time in the idle loop. Calls to IDL_run()
* are added to force the update of the Real-Time Analysis
* tools. Calls to IDL_run() are within a TSK_disable(),
* TSK_enable() block because the call to IDL_run()
* is not reentrant.

}
```
Tasks

Figure 4-12. Trace Window Results from Example 4-6

Figure 4-13. Execution Graph for Example 4-6
4.5 The Idle Loop

The idle loop is the background thread of DSP/BIOS, which runs continuously when no hardware interrupt service routines, software interrupt, or tasks are running. Any other thread can preempt the idle loop at any point.

The IDL Manager in the Configuration Tool allows you to insert functions that execute within the idle loop. The idle loop runs the IDL functions that you configured with the Configuration Tool. IDL_loop calls the functions associated with each one of the IDL objects one at a time, and then starts over again in a continuous loop. The functions are called in the same order in which they were created in the Configuration Tool. Therefore, an IDL function must run to completion before the next IDL function can start running. When the last idle function has completed, the idle loop starts the first IDL function again. Idle loop functions are often used to poll non-real-time devices that do not (or cannot) generate interrupts, monitor system status, or perform other background activities.

The idle loop is the thread with lowest priority in a DSP/BIOS application. The idle loop functions run only when no other hardware interrupts, software interrupts, or tasks need to run. Communication between the target and the DSP/BIOS Analysis Tools is performed within the background idle loop. This ensures that the DSP/BIOS Analysis Tools do not interfere with the program's processing. If the target CPU is too busy to perform background processes, the DSP/BIOS Analysis Tools stop receiving information from the target until the CPU is available.

By default, the idle loop runs the functions for these IDL objects:

- **LNK_dataPump** manages the transfer of real-time analysis data (for example, LOG and STS data), and HST channel data between the target DSP and the host. This is handled using RTDX.
  
  On the C54x platform, the RTDX_dataPump IDL object calls RTDX_Poll to transfer data between the target and the host. This occurs within the idle loop, which runs at the lowest priority.
  
  On the C55x and C6000 platforms, the host PC triggers an interrupt to transfer data to and from the target. This interrupt has a higher priority than SWI, TSK, and IDL functions. The actual HWI function runs in a very short time. Within the idle loop, the LNK_dataPump function does the more time-consuming work of preparing the RTDX buffers and performing the RTDX calls. Only the actual data transfer is done at high priority. This data transfer can have a small effect on real-time behavior, particularly if a large amount of LOG data must be transferred.
The Idle Loop

- **RTA_dispatcher** is a real-time analysis server on the target that accepts commands from DSP/BIOS Analysis Tools, gathers instrumentation information from the target, and uploads it at run time. RTA_dispatcher sits at the end of two dedicated HST channels; its commands/responses are routed from/to the host via LNK_dataPump.

- **IDL_cpuLoad** uses an STS object (IDL_busyObj) to calculate the target load. The contents of this object are uploaded to the DSP/BIOS Analysis Tools through RTA_dispatcher to display the CPU load.

- **RTDX_dataPump** calls RTDX_Poll on the C5400 platform to transfer data between the target and the host. This occurs only if the DSP has enough free cycles to execute the IDL loop on a regular basis. For the C55x and C6000 platforms, RTDX is an interrupt driven interface (as described for the LNK_dataPump object), and there is no RTDX_dataPump object.
4.6 Semaphores

DSP/BIOS provides a fundamental set of functions for intertask synchronization and communication based upon semaphores. Semaphores are often used to coordinate access to a shared resource among a set of competing tasks. The SEM module provides functions that manipulate semaphore objects accessed through handles of type SEM_Handle.

SEM objects are counting semaphores that can be used for both task synchronization and mutual exclusion. Counting semaphores keep an internal count of the number of corresponding resources available. When count is greater than 0, tasks do not block when acquiring a semaphore.

The functions SEM_create and SEM_delete are used to create and delete semaphore objects, respectively, as shown in Example 4-7. You can also use the Configuration Tool to create semaphore objects. See section 2.2.8, Creating, Referencing, and Deleting Dynamically-Created DSP/BIOS Objects, page 2-10, for a discussion of the benefits of creating objects with the Configuration Tool.

Example 4-7. Creating and Deleting a Semaphore

```c
SEM_Handle SEM_create(count, attrs);
Uns count;
SEM_Attrs *attrs;
Void SEM_delete(sem);
SEM_Handle sem;
```

The semaphore count is initialized to count when it is created. In general, count is set to the number of resources that the semaphore is synchronizing.

SEM_pend waits for a semaphore. If the semaphore count is greater than 0, SEM_pend simply decrements the count and returns. Otherwise, SEM_pend waits for the semaphore to be posted by SEM_post.

**Note:**

When called within an HWI, the code sequence calling SEM_post or SEM_ipost must be either wrapped within an HWI_enter/HWI_exit pair or invoked by the HWI dispatcher.

The timeout parameter to SEM_pend, as shown in Example 4-8, allows the task to wait until a timeout, to wait indefinitely (SYS_FOREVER), or to not wait at all (0). SEM_pend’s return value is used to indicate if the semaphore was acquired successfully.
Example 4-8. Setting a Timeout with SEM_pend

```c
Bool SEM_pend(sem, timeout);
SEM_Handle sem;
Uns   timeout; /* return after this many system clock ticks*/
```

Example 4-9 provides an example of SEM_post, which is used to signal a semaphore. If a task is waiting for the semaphore, SEM_post removes the task from the semaphore queue and puts it on the ready queue. If no tasks are waiting, SEM_post simply increments the semaphore count and returns.

Example 4-9. Signaling a Semaphore with SEM_post

```c
Void SEM_post(sem);
```

4.6.1 SEM Example

Example 4-10 provides sample code for three writer tasks which create unique messages and place them on a queue for one reader task. The writer tasks call SEM_post to indicate that another message has been enqueued. The reader task calls SEM_pend to wait for messages. SEM_pend returns only when a message is available on the queue. The reader task prints the message using the LOG_printf function.

The three writer tasks, reader task, semaphore, and queues in this example program were created with the Configuration Tool.

Since this program employs multiple tasks, a counting semaphore is used to synchronize access to the queue. Figure 4-14 provides a view of the results from Example 4-9. Though the three writer tasks are scheduled first, the messages are read as soon as they have been enqueued because the reader’s task priority is higher than that of the writer.
Example 4-10.  SEM Example Using Three Writer Tasks

```c
/*
 *  ======== semtest.c ========
 *
 *  Use a QUE queue and SEM semaphore to send messages from
 *  multiple writer() tasks to a single reader() task.  The
 *  reader task, the three writer tasks, queues, and semaphore
 *  are created by the Configuration Tool.
 *
 *  The MsgObj's are preallocated in main(), and put on the
 *  free queue.  The writer tasks get free message structures
 *  from the free queue, write the message, and then put the
 *  message structure onto the message queue.
 *  This example builds on quetest.c.  The major differences are:
 *  - one reader() and multiple writer() tasks.
 *  - SEM_pend() and SEM_post() are used to synchronize
 *    access to the message queue.
 *  - 'id' field was added to MsgObj to specify writer()
 *    task id.
 *
 *  Unlike a mailbox, a queue can hold an arbitrary number of
 *  messages or elements.  Each message must, however, be a
 *  structure with a QUE_Elem as its first field.
 */

extern LOG_Obj trace
```
Example 4.10. SEM Example Using Three Writer Tasks (continued)

```c
/*
 *       main       
*/
Void main()
{
    Int        i;
    MsgObj     *msg;
    Uns        mask;

    mask = TRC_LOGTSK | TRC_LOGSWI | TRC_STSSWI | TRC_LOGCLK;
    TRC_enable(TRC_GBLHOST | TRC_GBLTARG | mask);
    msg = (MsgObj *)MEM_alloc(0, NUMMSGS * sizeof(MsgObj), 0);
    if (msg == MEM_ILLEGAL) {
        SYS_abort("Memory allocation failed!
");
    }
    /* Put all messages on freequeue */
    for (i = 0; i < NUMMSGS; msg++, i++) {
        QUE_put(&freeQueue, msg);
    }
    /*       reader       */
    Void reader()
    {
        Msg         msg;
        Int i;
        for (i = 0; i < NUMMSGS * NUMWRITERS; i++) {
            /* Wait for semaphore to be posted by writer(). */
            SEM_pend(&sem, SYS_FOREVER);
            /* dequeue message */
            msg = QUE_get(&msgQueue);
            /* print value */
            LOG_printf(&trace, "read \"%c\" from \%(d).", msg->val, msg->id);
            /* free msg */
            QUE_put(&freeQueue, msg);
        }
        LOG_printf(&trace, "reader done.");
    }
```

Example 4.10.  SEM Example Using Three Writer Tasks (continued)

```c
/*
 *  ======== writer ========
 */
Void writer(Int id)
{
    Msg         msg;
    Int         i;

    for (i = 0; i < NUMMSGS; i++) {
        /*
        * Get msg from the free queue. Since reader is higher
        * priority and only blocks on sem, this queue is
        * never empty.
        */
        if (QUE_empty(&freeQueue)) {
            SYS_abort("Empty free queue!\n");
        }
        msg = QUE_get(&freeQueue);
        /* fill in value */
        msg->id = id;
        msg->val = (i & 0xf) + 'a';
        LOG_printf(&trace, "Task %d Done", (Arg)id);
        LOG_printf(&trace, "writer (%d) done.");
    }
}
```

Note:
Non-pointer type function arguments to LOG_printf need explicit type casting to (Arg) as shown in the following code example:

```c
LOG_printf(&trace, "Task %d Done", (Arg)id);
```

4.7 Mailboxes

The MBX module provides a set of functions to manage mailboxes. MBX mailboxes can be used to pass messages from one task to another on the same processor. An intertask synchronization enforced by a fixed length shared mailbox can be used to ensure that the flow of incoming messages does not exceed the ability of the system to process those messages. The examples given in this section illustrate just such a scheme.

The mailboxes managed by the MBX module are separate from the mailbox structure contained within a SWI object.

MBX_create and MBX_delete are used to create and delete mailboxes, respectively. You can also use the Configuration Tool to create mailbox objects. See section 2.2.8, Creating, Referencing, and Deleting Dynamically-Created DSP/BIOS Objects, page 2-10, for a discussion of the benefits of creating objects with the Configuration Tool.

You specify the mailbox length and message size when you create a mailbox as shown in Example 4-11.

**Example 4-11. Creating a Mailbox**

```c
MBX_Handle MBX_create(msgsize, mbxlength, attrs)
    Uns   msgsize;
    Uns   mbxlength;
    MBX_Attrs  *attrs;
Void MBX_delete(mbx)
    MBX_Handle     mbx;
```

MBX_pend is used to read a message from a mailbox as shown in Example 4-12. If no message is available (that is, the mailbox is empty), MBX_pend blocks. In this case, the timeout parameter allows the task to wait until a timeout, to wait indefinitely, or to not wait at all.

**Example 4-12. Reading a Message from a Mailbox**

```c
Bool MBX_pend(mbx, msg, timeout)
    MBX_Handle   mbx;
    Void   *msg;
    Uns    timeout;      /* return after this many */
    /* system clock ticks */
```

Conversely, MBX_post is used to post a message to the mailbox as shown in Example 4-13. If no message slots are available (that is, the mailbox is full), MBX_post blocks. In this case, the timeout parameter allows the task to wait until a timeout, to wait indefinitely, or to not wait at all.
Example 4-13. Posting a Message to a Mailbox

```c
Bool MBX_post(mbx, msg, timeout)
    MBX_Handle mbx;
    Void *msg;
    Uns   timeout;    /* return after this many */
    /* system clock ticks */
```

4.7.1 MBX Example

Example 4-14 provides sample code showing two types of tasks created with the Configuration Tool: a single reader task which removes messages from the mailbox, and multiple writer tasks which insert messages into the mailbox. The resultant trace from Example 4-14 is shown in Figure 4-15.

Note:

When called within an HWI, the code sequence calling MBX_post must be either wrapped within an HWI_enter/HWI_exit pair or invoked by the HWI dispatcher.
Example 4-14. **MBX Example With Two Types of Tasks**

```c
/*
  ======= mbxtest.c ========
  Use a MBX mailbox to send messages from multiple writer() tasks to a single reader() task.
  The mailbox, reader task, and 3 writer tasks are created by the Configuration Tool.
  
  This example is similar to semtest.c. The major differences are:
  - MBX is used in place of QUE and SEM.
  - the 'elem' field is removed from MsgObj.
  - reader() task is *not* higher priority than writer task.
  - reader() looks at return value of MBX_pend() for timeout
*/
#include <std.h>
#include <log.h>
#include <mbx.h>
#include <tsk.h>
#define NUMMSGS 3       /* number of messages */
#define TIMEOUT 10

typedef struct MsgObj {
    Int id;            /* writer task id */
    Char val;          /* message value */
} MsgObj, *Msg;

/* Mailbox created with Config Tool */
extern MBX_Obj mbx;

/* "trace" Log created with Config Tool */
extern LOG_Obj trace;

Void reader(Void);
Void writer(Int id);

/*
  ======= main =======
*/
Void main()
{ /* Does nothing */
}
```

Thread Scheduling 4-57
Example 4.14. **MBX Example With Two Types of Tasks (continued)**

```c
/* -*- reader -*-

Void reader(Void)
{
    MsgObj    msg;
    Int       i;

    for (i=0; ;i++) {
        /* wait for mailbox to be posted by writer() */
        if (MBX_pend(&mbx, &msg, TIMEOUT) == 0) {
            LOG_printf(&trace, "timeout expired for MBX_pend()");
            break;
        }

        /* print value */
        LOG_printf(&trace, "read \'\'c\'\' from (%d).", msg.val, msg.id);
    }

    LOG_printf(&trace, "reader done.");
}

/* -*- writer -*-

Void writer(Int id)
{
    MsgObj    msg;
    Int       i;

    for (i=0; i < NUMMSGS; i++) {
        /* fill in value */
        msg.id = id;
        msg.val = i % NUMMSGS + (Int)('a');

        LOG_printf(&trace, "(%d) writing \'\'c\'\' ...", id, (Int)msg.val);

        /* enqueue message */
        MBX_post(&mbx, &msg, TIMEOUT);

        /* what happens if you call TSK_yield() here? */
        /* TSK_yield(); */
    }

    LOG_printf(&trace, "writer (%d) done.", id);
}
```

After the program runs, review the trace log contents. The results should be similar to that shown in Example 4-15.
Associated with the mailbox at creation time is a total number of available message slots, determined by the mailbox length you specify when you create the mailbox. In order to synchronize tasks writing to the mailbox, a counting semaphore is created and its count is set to the length of the mailbox. When a task does an MBX_post operation, this count is decremented. Another semaphore is created to synchronize the use of reader tasks with the mailbox; this counting semaphore is initially set to zero so that reader tasks block on empty mailboxes. When messages are posted to the mailbox, this semaphore is incremented.

In Example 4-14, all the tasks have the same priority. The writer tasks try to post all their messages, but a full mailbox causes each writer to block indefinitely. The readers then read the messages until they block on an empty mailbox. The cycle is repeated until the writers have exhausted their supply of messages.
At this point, the readers pend for a period of time according to the following formula, and then time out:

\[
\text{TIMEOUT} \times \frac{1\text{ms}}{\text{clock ticks per millisecond}}
\]

After this timeout occurs, the pending reader task continues executing and then concludes.

At this point, it is a good idea to experiment with the relative effects of scheduling order and priority, the number of participants, the mailbox length, and the wait time by combining the following code modifications:

- Creation order or priority of tasks
- Number of readers and writers
- Mailbox length parameter (MBXLENGTH)
- Add code to handle a writer task timeout
DSPs typically have one or more on-device timers which generate a hardware interrupt at periodic intervals. DSP/BIOS normally uses one of the available on-device timers as the source for its own system clock. Using the on-device timer hardware present on most TMS320 DSPs, the CLK module supports time resolutions close to the single instruction cycle.

You define the system clock parameters in the DSP/BIOS configuration settings. In addition to the DSP/BIOS system clock, you can set up additional clock objects for invoking functions each time a timer interrupt occurs.

On the C6000 platform, you can also define parameters for the CLK module’s HWI object, since that object is pre-configured to use the HWI dispatcher. This allows you to manipulate the interrupt mask and cache control mask properties of the CLK ISR.

DSP/BIOS provides two separate timing methods—the high- and low-resolution times and the system clock. In the default configuration, the low-resolution time and the system clock are the same. However, your program can drive the system clock using some other event, such as the availability of data. You can disable or enable the CLK Manager’s use of the on-device timer to drive high- and low-resolution times. You can drive the system clock using the low-resolution time, some other event, or not at all. The interactions between these two timing methods are shown in Example 4-16.

**Figure 4-16. Interactions Between Two Timing Methods**

4.8.1 High- and Low-Resolution Clocks

Using the CLK Manager in the Configuration Tool, you can disable or enable DSP/BIOS’ use of an on-device timer to drive high- and low-resolution times on the Clock Manager Properties dialog box as shown in Figure 4-17, which depicts the CLK Manager Properties dialog box for the C54x platform.

The C6000 platform has multiple general-purpose timers, whereas, the C5400 platform has one general-purpose timer. On the C6000, the Configuration Tool allows you to select the on-device timer that is used by the CLK Manager. On all platforms, the Configuration Tool allows you to enter the period at which the timer interrupt is triggered. See CLK Module in the TMS320 DSP/BIOS API Reference Guide for your platform, for more details about these properties. By entering the period of the timer interrupt, DSP/BIOS automatically sets up the appropriate value for the period register.

Figure 4-17. CLK Manager Properties Dialog Box
When the CLK Manager is enabled on the C6000 platform, the timer counter register is incremented every four CPU cycles. When the CLK Manager is enabled on the C5400 platform, the timer counter is decremented at the following rate, where CLKOUT is the DSP clock speed in MIPS (see the Global Settings Property dialog in the TMS320 DSP/BIOS API Reference Guide for your platform) and TDDR is the value of the timer divide-down register as shown in the following equation.

\[
\text{CLKOUT} / (\text{TDDR} + 1)
\]

When this register reaches 0 on the C5400 platform, or the value set for the period register on the C6000 platform, the counter is reset. On the C5400, it is reset to the value in the period register. On the C6000, it is reset to 0. At this point, a timer interrupt occurs. When a timer interrupt occurs, the HWI object for the selected timer runs the CLK_F_isr function, which causes these events to occur:

- The low-resolution time is incremented by 1 on the C6000 platform and on the C5000 platform.
- All the functions specified by CLK objects are performed in sequence in the context of that ISR.

Therefore, the low-resolution clock ticks at the timer interrupt rate and the clock's time is equal to the number of timer interrupts that have occurred. To obtain the low-resolution time, you can call `CLK_getltime` from your application code.

The CLK functions performed when a timer interrupt occurs are performed in the context of the hardware interrupt that caused the system clock to tick. Therefore, the amount of processing performed within CLK functions should be minimized and these functions can invoke only DSP/BIOS calls that are allowable from within an HWI.

**Note:**

CLK functions should not call HWI_enter and HWI_exit as these are called internally when DSP/BIOS runs CLK_F_isr. Additionally, CLK functions should not use the `interrupt` keyword or the INTERRUPT pragma in C functions.
Timers, Interrupts, and the System Clock

The high-resolution clock ticks at the same rate the timer counter register is incremented on the C6000 platform and decremented on the C5400 platform. Hence, the high-resolution time is the number of times the timer counter register has been incremented or decremented. On the C6000 platform, this is equivalent to the number of instruction cycles divided by 4. The CPU clock rate is high, therefore, the timer counter register can reach the period register value (C6000 platform) or 0 (C5400 platform) very quickly.

On the C6000 platform, the 32-bit high-resolution time is calculated by multiplying the low-resolution time (that is, the interrupt count) by the value of the period register and adding the current value of the timer counter register. To obtain the value of the high-resolution time you can call CLK_gethtime from your application code. The value of both clock restart at 0 when the maximum 32-bit value is reached.

On the C54x platform, the 32-bit high-resolution time is calculated by multiplying the low-resolution time (that is, the interrupt count) by the value of the period register and adding the difference between the period register value and the value of the timer counter register. To obtain the value of the high-resolution time you can call CLK_gethtime from your application code. The value of the clock restarts at the value in the period register when 0 is reached.

Other CLK module APIs are CLK_getprd, which returns the value set for the period register in the Configuration Tool; and CLK_countspms, which returns the number of timer counter register increments or decrements per millisecond.

Modify the properties of the CLK Manager with the Configuration Tool (Figure 4-17) to configure the low-resolution clock. For example, to make the low-resolution clock tick every millisecond (.001 sec), type 1000 in the CLK Manager’s Microseconds/Int field. The Configuration Tool automatically calculates the correct value for the period register.

You can directly specify the period register value if you put a checkmark in the Directly configure on-device timer registers box as shown in Figure 4-17. On the C6000 platform, to generate a 1 millisecond (.001 sec) system clock period on a 160 MIPS processor using the CPU clock/4 to drive the clock, the period register value is:

\[
\text{Period} = 0.001 \text{ sec} \times 160,000,000 \text{ cycles per second} / 4 \text{ cycles} = 40,000
\]

To do the same thing on a C5400 platform with a 40 MIPS processor using the CPU to drive the clock, the period register value is:

\[
\text{Period} = 0.001 \text{ sec} \times 40,000,000 \text{ cycles per second} = 40,000
\]
4.8.2 System Clock

Many DSP/BIOS functions have a timeout parameter. DSP/BIOS uses a system clock to determine when these timeouts should expire. The system clock tick rate can be driven using either the low-resolution time or an external source.

The TSK_sleep function is an example of a function with a timeout parameter. After calling this function, its timeout expires when a number of ticks equal to the timeout value have passed in the system clock. For example, if the system clock has a resolution of 1 microsecond and we want the current task to block for 1 millisecond, the call should look like this:

/* block for 1000 ticks * 1 microsecond = 1 msec */
TSK_sleep(1000)

Note:
Do not call TSK_sleep or SEM_pend with a timeout other than 0 or SYS_FOREVER if the program is configured without something to drive the PRD module. In a default configuration, the CLK module drives the PRD module.

If you are using the default CLK configuration, the system clock has the same value as the low-resolution time because the PRD_clock CLK object drives the system clock.

There is no requirement that an on-device timer be used as the source of the system clock. An external clock, for example one driven by a data stream rate, can be used instead. If you do not want the on-device timer to drive the low-resolution time, use the Configuration Tool to delete the CLK object named PRD_clock. If an external clock is used, it can call PRD_tick to advance the system clock. Another possibility is having an on-device peripheral such as the codec that is triggering an interrupt at regular intervals, call PRD_tick from that interrupt’s HWI. In this case, the resolution of the system call is equal to the frequency of the interrupt that is calling PRD_tick.
4.8.3 Example—System Clock

Example 4-15, clktest.c, shows a simple use of the DSP/BIOS functions that use the system clock, TSK_time and TSK_sleep. The task, labeled task, in clktest.c sleeps for 1000 ticks before it is awakened by the task scheduler. Since no other tasks have been created, the program runs the idle functions while task is blocked. The program assumes that the system clock is configured and driven by PRD_clock. This program is included in the c:\target\examples\ folder where target represents your platform. The trace log output for the code in Example 4-15 would be similar to that shown in Example 4-18.

Example 4-15. Using the System Clock to Drive a Task

```c
/* ======== clktest.c ========
* In this example, a task goes to sleep for 1 sec and
* prints the time after it wakes up. */
#include <std.h>
#include <log.h>
#include <clk.h>
#include <tsk.h>
extern LOG_Obj trace;

/* ======== main ======== */
Void main()
{
    LOG_printf(&trace, "clktest example started.\n");
}

Void taskFxn()
{
    Uns ticks;
    LOG_printf(&trace, "The time in task is: %d ticks", (Int)TSK_time());
    ticks = (1000 * CLK_countspms()) / CLK_getprd();
    LOG_printf(&trace, "task going to sleep for 1 second... ");
    TSK_sleep(ticks);
    LOG_printf(&trace, "...awake! Time is: %d ticks", (Int)TSK_time());
}
```
Note:
Non-pointer type function arguments to LOG_printf need explicit type casting to (Arg) as shown in the following code example:

```
LOG_printf(&trace, "Task %d Done", (Arg)id);
```

**Figure 4-18. Trace Log Output from :Example 4-15**

```
Log Name: trace
0  clkttest example started.
1  The time in task is: 0 ticks
2  task going to sleep for 1 second...
3  ...awake! Time is: 1000 ticks
```
4.9 Periodic Function Manager (PRD) and the System Clock

Many applications need to schedule functions based on I/O availability or some other programmed event. Other applications can schedule functions based on a real-time clock.

The PRD Manager allows you to create objects that schedule periodic execution of program functions. To drive the PRD module, DSP/BIOS provides a system clock. The system clock is a 32-bit counter that ticks every time PRD_tick is called. You can use the timer interrupt or some other periodic event to call PRD_tick and drive the system clock.

There can be several PRD objects but all are driven by the same system clock. The period of each PRD object determines the frequency at which its function is called. The period of each PRD object is specified in terms of the system clock time; that is, in system clock ticks.

To schedule functions based on certain events, use the following procedures:

- **Based on a real-time clock.** Put a check mark in the Use CLK Manager to Drive PRD box by right-clicking on the PRD Manager and selecting Properties in the Configuration Tool. By doing this you are setting the timer interrupt used by the CLK Manager to drive the system clock. When you do this a CLK object called PRD_clock is added to the CLK module. This object calls PRD_tick every time the timer interrupt goes off, advancing the system clock by one tick.

**Note:**

When the CLK Manager is used to drive PRD, the system clock that drives PRD functions ticks at the same rate as the low-resolution clock. The low-resolution and system time coincide.

- **Based on I/O availability or some other event.** Remove the check mark from the Use the CLK Manager to Drive PRD box for the PRD Manager. Your program should call PRD_tick to increment the system clock. In this case the resolution of the system clock equals the frequency of the interrupt from which PRD_tick is called.
4.9.1 Invoking Functions for PRD Objects

When PRD_tick is called two things can occur:

- PRD_D_tick, the system clock counter, increases by one; that is, the system clock ticks.
- An SWI called PRD_swi is posted if the number of PRD_ticks that have elapsed is equal to a value that is the greatest power of two among the common denominators of the PRD function periods. For example, if the periods of three PRD objects are 12, 24, and 36, PRD_swi runs every four ticks. It does not simply run every 12 or 6 ticks because those intervals are not powers of two.

When a PRD object is created with the Configuration Tool, a new SWI object is automatically added called PRD_swi.

When PRD_swi runs, its function executes the following type of loop:

```c
for ("Loop through period objects"){
    if ("time for a periodic function")
        "run that periodic function";
}
```

Hence, the execution of periodic functions is deferred to the context of PRD_swi, rather than being executed in the context of the HWI where PRD_tick was called. As a result, there can be a delay between the time the system tick occurs and the execution of the periodic objects whose periods have expired with the tick. If these functions run immediately after the tick, you should configure PRD_swi to have a high priority with respect to other threads in your application.

4.9.2 Interpreting PRD and SWI Statistics

Many tasks in a real-time system are periodic; that is, they execute continuously and at regular intervals. It is important that such tasks finish executing before it is time for them to run again. A failure to complete in this time represents a missed real-time deadline. While internal data buffering can be used to recover from occasional missed deadlines, repeated missed deadlines eventually result in an unrecoverable failure.

The implicit statistics gathered for SWI functions measure the time from when a software interrupt is ready to run and the time it completes. This timing is critical because the processor is actually executing numerous hardware and software interrupts. If a software interrupt is ready to execute but must wait too long for other software interrupts to complete, the real-time deadline is missed. Additionally, if a task starts executing, but is interrupted too many times for too long a period of time, the real-time deadline is also missed.
The maximum ready-to-complete time is a good measure of how close the system is to potential failure. The closer a software interrupt's maximum ready-to-complete time is to its period, the more likely it is that the system cannot survive occasional bursts of activity or temporary data-dependent increases in computational requirements. The maximum ready-to-complete time is also an indication of how much headroom exists for future product enhancements (which invariably require more MIPS).

**Note:**

DSP/BIOS does not implicitly measure the amount of time each software interrupt takes to execute. This measurement can be determined by running the software interrupt in isolation using either the simulator or the emulator to count the precise number of execution cycles required.

It is important to realize even when the sum of the MIPS requirements of all routines in a system is well below the MIPS rating of the DSP, the system can not meet its real-time deadlines. It is not uncommon for a system with a CPU load of less than 70% to miss its real-time deadlines due to prioritization problems. The maximum ready-to-complete times monitored by DSP/BIOS, however, provide an immediate indication when these situations exist.

When statistics accumulators for software interrupts and periodic objects are enabled, the host automatically gathers the count, total, maximum, and average for the following types of statistics:

- **SWI.** Statistics about the period elapsed from the time the software interrupt was posted to its completion.

- **PRD.** The number of periodic system ticks elapsed from the time the periodic function is ready to run until its completion. By definition, a periodic function is ready to run when period ticks have occurred, where period is the *period* parameter for this object.

You can set the units for the SWI completion period by setting CLK Manager parameters. This period is measured in instruction cycles if the CLK module’s Use high resolution time for internal timings parameter is set to True (the default). If this CLK parameter is set to False, SWI statistics are displayed in units of timer interrupt periods. You can also choose milliseconds or microseconds for Statistics Units on the Statistics View Property Page.

For example, if the maximum value for a PRD object increases continuously, the object is probably not meeting its real-time deadline. In fact, the maximum value for a PRD object should be less than or equal to the period (in system ticks) property of this PRD object. If the maximum value is greater than the period (Figure 4-19), the periodic function has missed its real-time deadline.

4.10 Using the Execution Graph to View Program Execution

You can use the Code Composer Studio Execution Graph to see a visual display of thread activity by choosing DSP/BIOS→Execution Graph.

4.10.1 States in the Execution Graph Window

The Execution Graph, as seen in Figure 4-20, examines the information in the system log (LOG_system in the Configuration Tool) and shows the thread states in relation to the timer interrupt (Time) and system clock ticks (PRD Ticks).

Figure 4-20. The Execution Graph Window

White boxes indicate that a thread has been posted and is ready to run. Blue-green boxes indicate that the host had not yet received any information about the state of this thread at that point in the log. Dark blue boxes indicate that a thread is running.

Bright blue boxes in the Errors row indicate that an error has occurred. For example, an error is shown when the Execution Graph detects that a thread did not meet its real-time deadline. It also shows invalid log records, which can be caused by the program writing over the system log. Double-click on an error to see the details.
4.10.2 Threads in the Execution Graph Window

The SWI and PRD functions listed in the left column are listed from highest to lowest priority. However, for performance reasons, there is no information in the Execution Graph about hardware interrupt and background threads (aside from the CLK ticks, which are normally performed by an interrupt). Time not spent within an SWI, PRD, or TSK thread must be within an HWI or IDL thread, so this time is shown in the Other Threads row.

Functions run by PIP (notify functions) run as part of the thread that called the PIP API. The LNK_dataPump object runs a function that manages the host’s end of an HST (Host Channel Manager) object. This object and other IDL objects run from the IDL background thread, and are included in the Other Threads row.

**Note:**

The Time marks and the PRD Ticks are not equally spaced. This graph shows a square for each event. If many events occur between two Time interrupts or PRD Ticks, the distance between the marks is wider than for intervals during which fewer events occurred.

4.10.3 Sequence Numbers in the Execution Graph Window

The tick marks above the bottom scroll bar in Figure 4-20 show the sequence of events in the Execution Graph.

**Note:**

Circular logs (the default for the Execution Graph) contain only the most recent n events. Normally, there are events that are not listed in the log because they occur after the host polls the log and are overwritten before the next time the host polls the log. The Execution Graph shows a red vertical line and a break in the log sequence numbers at the end of each group of log events it polls.

You can view more log events by increasing the size of the log to hold the full sequence of events you want to examine. You can also set the RTA Control Panel to log only the events you want to examine.
4.10.4 RTA Control Panel Settings for Use with the Execution Graph

The TRC module allows you to control what events are recorded in the Execution Graph at any given time during the application execution. The recording of SWI, PRD, and CLK events in the Execution Graph can be controlled from the host (using the RTA Control Panel as shown in Figure 4-21; DSP/BIOS → RTA Control Panel in Code Composer Studio software) or from the target code (through the TRC_enable and TRC_disable APIs). See section 3.3.4.2, Control of Implicit Instrumentation, page 3-15, for details on how to control implicit instrumentation.

Figure 4-21. RTA Control Panel Dialog Box

When using the Execution Graph, turning off automatic polling stops the log from scrolling frequently and gives you time to examine the graph. You can use either of these methods to turn off automatic polling:

- Right-click on the Execution Graph and choose Pause from the shortcut menu.
- Right-click on the RTA Control Panel and choose Property Page. Set the Event Log/Execution Graph refresh rate to 0. Click OK.

You can poll log data from the target whenever you want to update the graph by right-clicking on the Execution Graph and choose Refresh Window from the shortcut menu. You can choose Refresh Window several times to see additional data. The shortcut menu you see when you right-click on the graph also allows you to clear the previous data shown on the graph.
If you plan to use the Execution Graph and your program has a complex execution sequence, you can increase the size of the Execution Graph in the Configuration Tool. Right-click on the LOG_system LOG object and select Properties to increase the buflen property. Each log message uses four words, so the buflen should be at least the number of events you want to store multiplied by 4.

In the case of the C55x platform, the large memory model data pointers are 23 bits in length and all long word access requires even address alignment. This results in the log event buffer size doubling (that is, eight words).
Chapter 5

Memory and Low-level Functions

This chapter describes the low-level functions found in the DSP/BIOS real-time multitasking kernel. These functions are embodied in three software modules: MEM, which manages allocation of memory; SYS, which provides miscellaneous system services; and QUE, which manages queues.

This chapter also presents several simple example programs that use these modules. The system primitives are described in greater detail in Chapter 1, in the TMS320 DSP/BIOS API Reference Guide for your platform.

5.1 Memory Management

The Memory Section Manager (MEM module) manages named memory segments that correspond to physical ranges of memory. If you want more control over memory segments, you can create your own linker command file and include the linker command file created by the Configuration Tool. It also provides a set of functions that can be used to dynamically allocate and free variable-sized blocks of memory.

Unlike standard C functions like malloc, the MEM functions enable you to specify which segment of memory is used to satisfy a particular request for storage. Real-time DSP hardware platforms typically contain several different types of memory: fast, on-device RAMs; zero wait-state external SRAMs; slower DRAMs for bulk data; and several others. Having explicit control over which memory segment contains a particular block of data is essential to meeting real-time constraints in many DSP applications.

The MEM module does not set or configure hardware registers associated with a DSPs memory subsystem. Such configuration is your responsibility and is typically handled by software loading programs, or in the case of Code Composer Studio, the GEL start-up or menu options. For example, to access external memory on a C6000 platform, the External Memory Interface (EMIF) registers must first be set appropriately before any access. The earliest opportunity for EMIF initialization within DSP/BIOS would be during the user initialization hook (see Global Settings in the TMS320 DSP/BIOS API Reference Guide for your platform).

The MEM functions allocate and free variable-sized memory blocks. Memory allocation and freeing are non-deterministic when using the MEM module, since this module maintains a linked list of free blocks for each particular memory segment. MEM_alloc and MEM_free must transverse this linked list when allocating and freeing memory.

5.1.1 Configuring Memory Segments

The templates provided with DSP/BIOS define a set of memory segments. These segments are somewhat different for each supported DSP board. If you are using a hardware platform for which there is no configuration template, you need to customize the MEM objects and their properties. You can customize MEM segments in the following ways:

- Insert a new MEM segment and define its properties. For details on MEM object properties, see the TMS320 DSP/BIOS API Reference Guide for your platform.
- Change the properties of an existing MEM segment.
Memory Management

- Delete some MEM segments, particularly those that correspond to external memory locations. However, you must first change any references to that segment made in the properties of other objects and managers. To find dependencies on a particular MEM segment, right-click on that segment and select Show Dependencies from the pop-up menu. Deleting or renaming the IPRAM and IDRAM (C6000 platform) or IPROG and IDATA (C5000 platform) segments is not recommended.

- Rename some MEM segments. To rename a segment, follow these steps:
  a) Remove dependencies to the segment you want to rename. To find dependencies on a particular MEM segment, right-click on that segment and select Show Dependencies from the pop-up menu.
  b) Rename the segment. You can right-click on the segment name and choose Rename from the pop-up menu to edit the name.
  c) Recreate dependencies on this segment as needed by selecting the new segment name in the property dialogs for other objects.

5.1.2 Disabling Dynamic Memory Allocation

If small code size is important to your application, you can reduce code size significantly by removing the capability to dynamically allocate and free memory. If you remove this capability, your program cannot call any of the MEM functions or any object creation functions (such as TSK_create). You should create all objects that are used by your program with the Configuration Tool.

To remove the dynamic memory allocation capability, put a checkmark in the No Dynamic Memory Heaps box in the Properties dialog for the MEM Manager.

If dynamic memory allocation is disabled and your program calls a MEM function (or indirectly calls a MEM function by calling an object creation function), an error occurs. If the segid passed to the MEM function is the name of a segment, a link error occurs. If the segid passed to the MEM function is an integer, the MEM function will call SYS_error.

5.1.3 Defining Segments in Your Own Linker Command File

The MEM Manager allows you to select which memory segment contains various types of code and data. If you want more control over where these items are stored, put a checkmark in the User .cmd file for non-DSP/BIOS segments box in the Properties dialog for the MEM Manager.
Memory Management

You should then create your own linker command file that begins by including the linker command file created by the Configuration Tool. For example, your own linker command file might look like one of those shown in Example 5-1 or Example 5-2.

Example 5-1. Linker Command File (C6000 Platform)

```c
/* First include DSP/BIOS generated cmd file. */
-l designcfg.cmd

SECTIONS {
    /* place high-performance code in on-device ram */
    .fast_text: {
        myfastcode.lib*(.text)
        myfastcode.lib*(.switch)
    } > IPRAM

    /* all other user code in off device ram */
    .text: {} > SDRAM0
    .switch: {} > SDRAM0
    .cinit: {} > SDRAM0
    .pinit: {} > SDRAM0

    /* user data in on-device ram */
    .bss: {} > IDRAM
    .far: {} > IDRAM
}
```

Example 5-2. Linker Command File (C5000 Platform)

```c
/* First include DSP/BIOS generated cmd file. */
-l designcfg.cmd

SECTIONS {
    /* place high-performance code in on-device ram */
    .fast_text: {
        myfastcode.lib*(.text)
        myfastcode.lib*(.switch)
    } > IPROG PAGE 0

    /* all other user code in off device ram */
    .text: {} > EPROG0 PAGE 0
    .switch: {} > EPROG0 PAGE 0
    .cinit: {} > EPROG0 PAGE 0
    .pinit: {} > EPROG0 PAGE 0

    /* user data in on-device ram */
    .bss: {} > IDATA PAGE 1
    .far: {} > IDATA PAGE 1
}
```
5.1.4 Allocating Memory Dynamically

Basic system-level storage allocation is handled by MEM_alloc, whose parameters specify a memory segment, a block size, and an alignment as shown in Example 5-3. If the memory request cannot be satisfied, MEM_alloc returns MEM_ILLEGAL.

Example 5-3. Using MEM_alloc for System-Level Storage

```
Ptr MEM_alloc(segid, size, align)
    Int segid;
    Uns size;
    Uns align;
```

The segid parameter identifies the memory segment from which memory is to be allocated. This identifier can be an integer or a memory segment name defined in the Configuration Tool.

The memory block returned by MEM_alloc contains at least the number of minimum addressable data units (MADUs) indicated by the size parameter. A minimum addressable unit for a processor is the smallest datum that can be loaded or stored in memory. An MADU can be viewed as the number of bits between consecutive memory addresses. The number of bits in an MADU varies with different DSP devices, for example, the MADU for the C5000 platform is a 16-bit word, and the MADU for the C6000 platform is an 8-bit byte.

The memory block returned by MEM_alloc starts at an address that is a multiple of the align parameter; no alignment constraints are imposed if align is 0. An array of structures might be allocated as shown in Example 5-4.

Example 5-4. Allocating an Array of Structures

```
typedef struct Obj {
    Int    field1;
    Int    field2;
    Ptr    objArr;
} Obj;

objArr = MEM_alloc(SRAM, sizeof(Obj) * ARRAYLEN, 0);
```

Many DSP algorithms use circular buffers that can be managed more efficiently on most DSPs if they are aligned on a power of 2 boundary. This buffer alignment allows the code to take advantage of circular addressing modes found in many DSPs.
If no alignment is necessary, align should be 0. MEM’s implementation aligns memory on a boundary equal to the number of words required to hold a MEM_Header structure, even if align has a value of 0. Other values of align cause the memory to be allocated on an align word boundary, where align is a power of 2.

5.1.5 Freeing Memory

MEM_free frees memory obtained with a previous call to MEM_alloc, MEM_calloc, or MEM_valloc. The parameters to MEM_free—segid, ptr, and size—specify a memory segment, a pointer, and a block size respectively, as shown in Example 5-5. The values of these parameters must be the same as those used when allocating the block of storage.

Example 5-5. Using MEM_free to Free Memory

```c
Void MEM_free(segid, ptr, size)
    Int segid;
    Ptr ptr;
    Uns size;
```

Example 5-6 displays a function call which frees the array of objects allocated in Example 5-5.

Example 5-6. Freeing an Array of Objects

```c
MEM_free(SRAM, objArr, sizeof(Obj) * ARRAYLEN);
```

5.1.6 Getting the Status of a Memory Segment

You can use MEM_stat to obtain the status of a memory segment in the number of minimum addressable data units (MADUs). In a manner similar to MEM_alloc, MEM_calloc, and MEM_valloc (refer to Example 5-3), the size used and length values are returned by MEM_stat.

5.1.7 Reducing Memory Fragmentation

Repeatedly allocating and freeing blocks of memory can lead to memory fragmentation. When this occurs, calls to MEM_alloc can return MEM_ILLEGAL if there is no contiguous block of free memory large enough to satisfy the request. This occurs even if the total amount of memory in free memory blocks is greater than the amount requested.
To minimize memory fragmentation, you can use separate memory segments for allocations of different sizes as shown in Figure 5-1.

Figure 5-1. Allocating Memory Segments of Different Sizes

<table>
<thead>
<tr>
<th>Segment #</th>
<th>Target Memory</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Allocate small blocks from one segment for messages</td>
</tr>
<tr>
<td>1</td>
<td>Allocate large blocks from another segment for streams</td>
</tr>
</tbody>
</table>

Note:
To minimize memory fragmentation, allocate smaller, equal-sized blocks of memory from one memory segment and larger equal-sized blocks of memory from a second segment.

5.1.8 MEM Example

Example 5-7 and Example 5-8 use the functions MEM_stat, MEM_alloc, and MEM_free to highlight several issues involved with memory allocation. Figure 5-2 shows the trace window results from Example 5-7 or Example 5-8.

In Example 5-7 and Example 5-8, memory is allocated from IDATA and IDRAM memory using MEM_alloc, and later freed using MEM_free. printmem is used to print the memory status to the trace buffer. The final values (for example, “after freeing...”) should match the initial values.
Example 5-7. Memory Allocation (C5000 Platform)

```c
/* --------- memtest.c ---------
 * This code allocates/frees memory from different memory segments.
 */

#include <std.h>
#include <log.h>
#include <mem.h>

#define NALLOCS 2  /* # of allocations from each segment */
#define BUFSIZE 128 /* size of allocations */

/* "trace" Log created by Configuration Tool */
extern LOG_Obj trace;
#ifdef -54-
extern Int IDATA;
#endif
#ifdef -55-
extern Int DATA;
#endif
static Void printmem(Int segid);
/*
 * --------- main ---------
 */
Void main()
{
  Int i;
  Ptr ram[NALLOCS];
  LOG_printf(&trace, "before allocating ...");
  /* print initial memory status */
  printmem();
  LOG_printf(&trace, "allocating ...");
  /* allocate some memory from each segment */
  for (i = 0; i < NALLOCS; i++) {
    ram[i] = MEM_alloc(, BUFSIZE, 0);
    LOG_printf(&trace, "seg %d: ptr = 0x%x", , ram[i]);
  }
  LOG_printf(&trace, "after allocating ...");
  /* print memory status */
  printmem();
  /* free memory */
  for (i = 0; i < NALLOCS; i++) {
    MEM_free(, ram[i], BUFSIZE);
  }
  LOG_printf(&trace, "after freeing ...");
  /* print memory status */
  printmem();
}

/*
 * --------- printmem ---------
 */
static Void printmem(Int segid)
{
  MEM_Stat statbuf;
  MEM_stat(segid, &statbuf);
  LOG_printf(&trace, "seg %d: O 0x%x", segid, statbuf.size);
  LOG_printf(&trace, "U 0x%x A 0x%x", statbuf.used, statbuf.length);
}
```
Note:
Non-pointer type function arguments to LOG_printf need explicit type casting to (Arg) as shown in the following code example:

```c
LOG_printf(&trace, "Task %d Done", (Arg)id);
```

Example 5-8. Memory Allocation (C6000 Platform)

```c
/* ======== memtest.c ========
* This program allocates and frees memory from different memory segments.
*/
#include <std.h>
#include <log.h>
#include <mem.h>
#define NALLOCS 2       /* # of allocations from each segment */
#define BUFSIZE 128     /* size of allocations */

/* "trace" Log created by Configuration Tool */
extern LOG_Obj trace;
extern Int IDRAM;
static Void printmem(Int segid);

/* ======== main ========
*/
Void main()
{
  Int i;
  Ptr ram[NALLOCS];
  LOG_printf(&trace, "before allocating ..."★★★★★);
  /* print initial memory status */
  printmem();
  LOG_printf(&trace, "allocating ..."★★★★★);
  /* allocate some memory from each segment */
  for (i = 0; i < NALLOCS; i++) {
    ram[i] = MEM_alloc(, BUFSIZE, 0);
    LOG_printf(&trace, "seg %d: ptr = 0x%x", , ram[i]);
    MEM_stat(segid, &statbuf);
    LOG_printf(&trace, "seg %d: O 0x%x\tU 0x%x\tA 0x%x\tU 0x%x\tA 0x%x", segid, statbuf.size, statbuf.used, statbuf.length);
  }
  LOG_printf(&trace, "after allocating ..."★★★★★);
  /* print memory status */
  printmem();
  /* free memory */
  for (i = 0; i < NALLOCS; i++) {
    MEM_free(, ram[i], BUFSIZE);
    LOG_printf(&trace, "after freeing ..."★★★★★);
    /* print memory status */
    printmem();
  }
  /* print memory status */
  printmem();
}

/* ======== printmem ========
*/
static Void printmem(Int segid)
{
  MEM_Stat statbuf;
  MEM_stat(segid, &statbuf);
  LOG_printf(&trace, "\tU 0x%x\tA 0x%x", statbuf.used, statbuf.length);
}
```
The program in Example 5-7 and Example 5-8 gives board-dependent results. O indicates the original amount of memory, U the amount of memory used, and A the length in MADUs of the largest contiguous free block of memory. The addresses you see are likely to differ from those shown in Example 5-2.
5.2 System Services

The SYS module provides a basic set of system services patterned after similar functions normally found in the standard C run-time library. As a rule, DSP/BIOS software modules use the services provided by SYS in lieu of similar C library functions.

Using the Configuration Tool, you can specify a customized routine that performs when the program calls one of these SYS functions. See the SYS reference section in the TMS320 DSP/BIOS API Reference Guide for your platform for details.

5.2.1 Halting Execution

SYS provides two functions as seen in Example 5-9 for halting program execution: SYS_exit, which is used for orderly termination; and SYS_abort, which is reserved for catastrophic situations. Since the actions that should be performed when exiting or aborting programs are inherently system-dependent, you can modify configuration settings to invoke your own routines whenever SYS_exit or SYS_abort is called.

Example 5-9. Coding To Halt Program Execution with SYS_exit or SYS_abort

```
Void SYS_exit(status)
    Int status;

Void SYS_abort(format, [arg,] ...)
    String  format;
    Arg arg;
```

The functions in Example 5-9 terminate execution by calling whatever routine is specified for the Exit function and Abort function properties of the SYS module. The default exit function is UTL_halt. The default abort function is _UTL_doAbort, which logs an error message and calls _halt. The _halt function is defined in the boot.c file; it loops infinitely with all processor interrupts disabled.

SYS_abort accepts a format string plus an optional set of data values (presumably representing a diagnostic message), which it passes to the function specified for the Abort function property of the SYS module as shown in Example 5-10.
Example 5-10. Using SYS_abort with Optional Data Values

\[
(*\text{(Abort\_function)})\ (\text{format, vars})
\]

The single vars parameter is of type va_list and represents the sequence of
arg parameters originally passed to SYS_abort. The function specified for the
Abort function property can pass the format and vars parameters directly to
SYS_vprintf or SYS_vsprintf prior to terminating program execution. To avoid
the large code overhead of SYS_vprintf or SYS_vsprintf, you can use
LOG_error instead to simply print the format string.

SYS_exit likewise calls whatever function is bound to the Exit function
property, passing on its original status parameter. SYS_exit first executes a
set of handlers registered through the function SYS_atexit as described
Example 5-11.

Example 5-11. Using Handlers in SYS_exit

\[
(*\text{handlerN})(\text{status})
\]
\[
\ldots
\]
\[
(*\text{handler2})(\text{status})
\]
\[
(*\text{handler1})(\text{status})
\]
\[
(*\text{(Exit\_function)})(\text{status})
\]

The function SYS_atexit provides a mechanism that enables you to stack up
to SYS_NUMHANDLERS (which is set to 8) clean-up routines as shown in
Example 5-12. The handlers are executed before SYS_exit calls the function
bound to the Exit function property. SYS_atexit returns FALSE when its
internal stack is full.

Example 5-12. Using Multiple SYS_NUMHANDLERS

\[
\text{Bool SYS\_atexit}(\text{handler})
\]
\[
\text{Fxn handler;}
\]
5.2.2 Handling Errors

SYS_error is used to handle DSP/BIOS error conditions as shown in Example 5-13. Application programs as well as internal functions use SYS_error to handle program errors.

Example 5-13. DSP/BIOS Error Handling

```c
Void SYS_error(s, errno, ...)
    String s;
    Uns   errno;
```

SYS_error uses whatever function is bound to the Error function property to handle error conditions. The default error function in the configuration template is _UTL_doError, which logs an error message. In Example 5-14, Error function can be configured to use doError which uses LOG_error to print the error number and associated error string.

Example 5-14. Using doError to Print Error Information

```c
Void doError(String s, Int errno, va_list ap)
{
    LOG_error("SYS_error called: error id = 0x%x", errno);
    LOG_error("SYS_error called: string = "%s", s);
}
```

The errno parameter to SYS_error can be a DSP/BIOS error (for example, SYS_EALLOC) or a user error (errno >= 256). See TMS320 DSP/BIOS API Reference Guide for your platform for a table of error codes and strings.
5.3 Queues

The QUE module provides a set of functions to manage a list of QUE elements. Though elements can be inserted or deleted anywhere within the list, the QUE module is most often used to implement a FIFO list—elements are inserted at the tail of the list and removed from the head of the list. QUE elements can be any structure whose first field is of type QUE_Elem. In Example 5-15, QUE_Elem is used by the QUE module to enqueue the structure while the remaining fields contain the actual data to be enqueued.

QUE_create and QUE_delete are used to create and delete queues, respectively. Since QUE queues are implemented as linked lists, queues have no maximum size. This is also shown in Example 5-15.

Example 5-15. Managing QUE Elements Using Queues

```c
typedef struct QUE_Elem {
    struct QUE_Elem *next;
    struct QUE_Elem *prev;
} QUE_Elem;

typedef struct MsgObj {
    QUE_Elem   elem;
    Char       val;
} MsgObj;

QUE_Handle QUE_create(attrs)
    QUE_Attrs  *attrs;
Void QUE_delete(queue)
    QUE_Handle queue;
```

5.3.1 Atomic QUE Functions

QUE_put and QUE_get are used to atomically insert an element at the tail of the queue or remove an element from the head of the queue. These functions are atomic in that elements are inserted and removed with interrupts disabled. Therefore, multiple threads can safely use these two functions to modify a queue without any external synchronization.

QUE_get atomically removes and returns the element from the head of the queue, whereas, QUE_put atomically inserts the element at the tail of the queue. In both functions, the queue element has type Ptr to avoid unnecessary type casting as shown in Example 5-16.
5.3.2 Other QUE Functions

Unlike QUE_get and QUE_put, there are a number of QUE functions that do not disable interrupts when updating the queue. These functions must be used in conjunction with some mutual exclusion mechanism if the queues being modified are shared by multiple threads.

QUE_dequeue and QUE_enqueue are equivalent to QUE_get and QUE_put except that they do not disable interrupts when updating the queue.

QUE_head is used to return a pointer to the first element in the queue without removing the element. QUE_next and QUE_prev are used to scan the elements in the queue—QUE_next returns a pointer to the next element in the queue and QUE_prev returns a pointer to the previous element in the queue.

QUE_insert and QUE_remove are used to insert or remove an element from an arbitrary point within the queue.
Example 5-17. Using QUE Functions with Mutual Exclusion Elements

<table>

<tr>
<td></td>
<td>Insert an element into the queue before the next element</td>
</tr>
<tr>
<td>Void QUE_remove(qelem)</td>
<td>Remove the specified element from the queue</td>
</tr>
</tbody>
</table>

Note:
Since QUE queues are implemented as doubly linked lists with a header node, it is possible for QUE_head, QUE_next, or QUE_prev to return a pointer to the header node itself (for example, calling QUE_head on an empty queue). Be careful not to call QUE_remove and remove this header node.

5.3.3 QUE Example

Example 5-18 uses a QUE queue to send five messages from a writer to a reader task. The functions MEM_alloc and MEM_free are used to allocate and free the MsgObj structures.

The program in Example 5-18 yields the results shown in Figure 5-3. The writer task uses QUE_put to enqueue each of its five messages and then the reader task uses QUE_get to dequeue each message.
Example 5-18. Using QUE to Send Messages

/*
 * ======== quetest.c ========
 * Use a QUE queue to send messages from a writer to a reader.
 * The queue is created by the Configuration Tool.
 * For simplicity, we use MEM_alloc and MEM_free to manage
 * the MsgObj structures. It would be way more efficient to
 * preallocate a pool of MsgObj’s and keep them on a ‘free’
 * queue. Using the Config Tool, create ‘freeQueue’. Then in
 * main, allocate the MsgObj’s with MEM_alloc and add them to
 * ‘freeQueue’ with QUE_put.
 * You can then replace MEM_alloc calls with QUE_get(freeQueue)
 * and MEM_free with QUE_put(freeQueue, msg).
 * A queue can hold an arbitrary number of messages or elements.
 * Each message must, however, be a structure with a QUE_Elem as
 * its first field.
 */

#include <std.h>
#include <log.h>
#include <mem.h>
#include <que.h>
#include <sys.h>

#define NUMMSGS 5 /* number of messages */

typedef struct MsgObj {
    QUE_Elem elem; /* first field for QUE */
    Char val; /* message value */
} MsgObj, *Msg;

extern QUE_Obj queue;
extern LOG_Obj trace;

Void reader();
Void writer();

/*
 * ======== main ========
 */
Void main()
{
    /*
     * Writer must be called before reader to ensure that the
     * queue is non-empty for the reader.
     */
    writer();
    reader();
}
Example 5.18. Using QUE to Send Messages (continued)

```c
/*   --------- reader ---------   */
Void reader()
{
    Msg    msg;
    Int    i;
    for (i=0; i < NUMMSGS; i++) {
        // The queue should never be empty *
        if (QUE_empty(&queue)) {
            SYS_abort("queue error\n");
        }
        // dequeue message */
        msg = QUE_get(&queue);
        /* print value */
        LOG_printf(&trace, "read '%c'.", msg->val);
        /* free msg */
        MEM_free(0, msg, sizeof(MsgObj));
    }
}

/*   --------- writer ---------   */
Void writer()
{
    Msg    msg;
    Int    i;
    for (i=0; i < NUMMSGS; i++) {
        // allocate msg */
        msg = MEM_alloc(0, sizeof(MsgObj), 0);
        if (msg == MEM_ILLEGAL) {
            SYS_abort("Memory allocation failed!\n");
        }
        /* fill in value */
        msg->val = i + 'a';
        LOG_printf(&trace, "writing '%c' ...", msg->val);
        /* enqueue message */
        QUE_put(&queue, msg);
    }
}
```

Note:
Non-pointer type function arguments to log_printf need explicit type casting to (Arg) as shown in the following code example:

```c
LOG_printf(&trace, "Task %d Done", (Arg)id);
```

6.1 I/O Overview

Input and output for DSP/BIOS applications are handled by stream, pipe, and host channel objects. Each type of object has its own module for managing data input and output.

A stream is a channel through which data flows between an application program and an I/O device. This channel can be read-only (input) or write-only (output) as shown in Figure 6-1. Streams provide a simple and universal interface to all I/O devices, allowing the application to be completely ignorant of the details of an individual device’s operation.

Figure 6-1. Input/Output Stream

An important aspect of stream I/O is its asynchronous nature. Buffers of data are input or output concurrently with computation. While an application is processing the current buffer, a new input buffer is being filled and a previous one is being output. This efficient management of I/O buffers allows streams to minimize copying of data. Streams exchange pointers rather than data, thus reducing overhead and allowing programs to meet real-time constraints more readily.

A typical program gets a buffer of input data, processes the data, and then outputs a buffer of processed data. This sequence repeats over and over, usually until the program is terminated.

Digital-to-analog converters, video frame grabbers, transducers, and DMA channels are just a few examples of common I/O devices. The stream module (SIO) interacts with these different types of devices through drivers (managed by the DEV module) that use the DSP/BIOS programming interface.

Device drivers are software modules that manage a class of devices. For example, two common classes are serial ports and parallel ports. These modules follow a common interface (provided by DEV) so stream functions can make generic requests, the drivers execute in whatever manner is appropriate for the particular class of devices.
Figure 6-2 depicts the interaction between streams and devices. The shaded area illustrates the material covered by this chapter: the stream portion of this interaction, handled by the SIO module. Chapter 7 discusses the DEV module and the relationship of streams with devices.

Figure 6-2. Interaction Between Streams and Devices

Data pipes are used to buffer streams of input and output data. These data pipes provide a consistent software data structure you can use to drive I/O between the DSP device and all kinds of real-time peripheral devices. There is more overhead with a data pipe than with streams, and notification is automatically handled by the pipe manager. All I/O operations on a pipe deal with one frame at a time; although each frame has a fixed length, the application can put a variable amount of data in each frame up to the length of the frame.

Separate pipes should be used for each data transfer thread, and a pipe should only have a single reader and a single writer, providing point to point communication. Often one end of a pipe is controlled by an HWI and the other end is controlled by an SWI function. Pipes can also transfer data between two application threads.

Host channel objects allow an application to stream data between the target and the host. Host channels are statically configured for input or output. Each host channel is internally implemented using a data pipe object.
6.2 Comparing Pipes and Streams

DSP/BIOS supports two different models for data transfer. The pipe model is used by the PIP and HST modules. The stream model is used by the SIO and DEV modules.

Both models require that a pipe or stream have a single reader thread and a single writer thread. Both models transfer buffers within the pipe or stream by copying pointers rather than by copying data between buffers.

In general, the pipe model supports low-level communication, while the stream model supports high-level, device-independent I/O. Table 6-1 compares the two models in more detail.

</tbody>
</table>
6.3 Data Pipe Manager (PIP Module)

Pipes are designed to manage block I/O (also called stream-based or asynchronous I/O). Each pipe object maintains a buffer divided into a fixed number of fixed length frames, specified by the numframes and framesize properties. All I/O operations on a pipe deal with one frame at a time. Although each frame has a fixed length, the application can put a variable amount of data in each frame (up to the length of the frame).

As shown in Figure 6-3, a pipe has two ends. The writer end is where the program writes frames of data. The reader end is where the program reads frames of data.

Figure 6-3. The Two Ends of a Pipe

Data notification functions (notifyReader and notifyWriter) are performed to synchronize data transfer. These functions are triggered when a frame of data is read or written to notify the program that a frame is free or data is available. These functions are performed in the context of the function that calls PIP_free or PIP_put. They can also be called from the thread that calls PIP_get or PIP_alloc. When PIP_get is called, DSP/BIOS checks whether there are more full frames in the pipe. If so, the notifyReader function is executed. When PIP_alloc is called, DSP/BIOS checks whether there are more empty frames in the pipe. If so, the notifyWriter function is executed.

A pipe should have a single reader and a single writer. Often, one end of a pipe is controlled by an HWI and the other end is controlled by a software interrupt function. Pipes can also be used to transfer data within the program between two application threads.

During program startup (which is described in detail in section 2.6, DSP/BIOS Startup Sequence, page 2-20), the BIOS_start function enables the DSP/BIOS modules. As part of this step, the PIP_startup function calls the notifyWriter function for each pipe object, since at startup all pipes have available empty frames.
There are no special format or data type requirements for the data to be transferred by a pipe.

The online help in the Configuration Tool describes data pipe objects and their parameters. See PIP Module in the TMS320 DSP/BIOS API Reference Guide for your platform for information on the PIP module API.

### 6.3.1 Writing Data to a Pipe

The steps that a program should perform to write data to a pipe are as follows:

1) A function should first check the number of empty frames available to be filled with data. To do this, the program must check the return value of PIP_getWriterNumFrames. This function call returns the number of empty frames in a pipe object.

2) If the number of empty frames is greater than 0, the function then calls PIP_alloc to get an empty frame from the pipe.

3) Before returning from the PIP_alloc call, DSP/BIOS checks whether there are additional empty frames available in the pipe. If so, the notifyWriter function is called at this time.

4) Once PIP_alloc returns, the empty frame can be used by the application code to store data. To do this the function needs to know the frame's start address and its size. The API function PIP_getWriterAddr returns the address of the beginning of the allocated frame. The API function PIP_getWriterSize returns the number of words that can be written to the frame. (The default value for an empty frame is the configured frame size.)

5) When the frame is full of data, it can be returned to the pipe. If the number of words written to the frame is less than the frame size, the function can specify this by calling the PIP_setWriterSize function. Afterwards, call PIP_put to return the data to the pipe.

6) Calling PIP_put causes the notifyReader function to run. This enables the writer thread to notify the reader thread that there is data available in the pipe to be read.

The code fragment in Figure 6-1 demonstrates how to write data to a pipe.
Example 6-1 Writing Data to a Pipe

```c
extern far PIP_Obj writerPipe; /* pipe object created with*/
/* the Configuration Tool */

writer()
{
    Uns size;
    Uns newsize;
    Ptr addr;

    if (PIP_getWriterNumFrames(&writerPipe) > 0) {
        PIP_alloc(&writerPipe); /* allocate an empty frame */
    } else {
        return; /* There are no available empty frames */
    }

    addr = PIP_getWriterAddr(&writerPipe);
    size = PIP_getWriterSize(&writerPipe);

    ' fill up the frame '
    /* optional */
    newsize = 'number of words written to the frame';
    PIP_setWriterSize(&writerPipe, newsize);
    /* release the full frame back to the pipe */
    PIP_put(&writerPipe);
}
```

6.3.2 Reading Data from a Pipe

To read a full frame from a pipe, a program should perform the following steps:

1) The function should first check the number of full frames available to be read from the pipe. To do this, the program must check the return value of PIP_getReaderNumFrames. This function call returns the number of full frames in a pipe object.

2) If the number of full frames is greater than 0, the function then calls PIP_get to get a full frame from the pipe.

3) Before returning from the PIP_get call, DSP/BIOS checks whether there are additional full frames available in the pipe. If so, the notifyReader function is called at this time.

4) Once PIP_get returns, the data in the full frame can be read by the application. To do this the function needs to know the frame’s start address and its size. The API function PIP_getReaderAddr returns the address of the beginning of the full frame. The API function PIP_getReaderSize returns the number of valid data words in the frame.
5) When the application has finished reading all the data, the frame can be returned to the pipe by calling PIP_free.

6) Calling PIP_free causes the notifyWriter function to run. This enables the reader thread to notify the writer thread that there is a new empty frame available in the pipe.

The code fragment in Example 6-2 demonstrates how to read data from a pipe.

Example 6-2 Reading Data from a Pipe

```c
extern far PIP_Obj readerPipe; /* created with the */
    /* Configuration Tool */
reader()
{
    Uns size;
    Ptr addr;
    if (PIP_getReaderNumFrames(&readerPipe) > 0) {
        PIP_get(&readerPipe); /* get a full frame */
    } else {
        return; /* There are no available full frames */
    }
    addr = PIP_getReaderAddr(&readerPipe);
    size = PIP_getReaderSize(&readerPipe);
    /* read the data from the frame */
    /* release the empty frame back to the pipe */
    PIP_free(&readerPipe);
}
```

6.3.3 Using a Pipe's Notify Functions

The reader or writer threads of a pipe can operate in a polled mode and directly test the number of full or empty frames available before retrieving the next full or empty frame. The examples in section 6.3.1, Writing Data to a Pipe, page 6-6, and section 6.3.2, Reading Data from a Pipe, page 6-7, demonstrate this type of polled read and write operation.

When used to buffer real-time I/O streams written (read) by a hardware peripheral, pipe objects often serve as a data channel between the HWI routine triggered by the peripheral itself and the program function that ultimately reads (writes) the data. In such situations, the application can effectively synchronize itself with the underlying I/O stream by configuring the pipe's notifyReader (notifyWriter) function to automatically post a software interrupt that runs the reader (writer) function.
When the HWI routine finishes filling up (reading) a frame and calls PIP_put (PIP_free), the pipe’s notify function can be used to automatically post a software interrupt. In this case, rather than polling the pipe for frame availability, the reader (writer) function runs only when the software interrupt is triggered; that is, when frames are available to be read (written).

Such a function would not need to check for the availability of frames in the pipe, since it is called only when data is ready. As a precaution, the function can still check whether frames are ready, and if not, cause an error condition, as in the following example code

\[
\text{if (PIP_getReaderNumFrames(&readerPipe) = 0) \{ }
\text{\quad error(); /* reader function should not have been posted! */ }
\text{\}}
\]

Hence, the notify function of pipe objects can serve as a flow-control mechanism to manage I/O to other threads and hardware devices.

### 6.3.4 Calling Order for PIP APIs

Each pipe object internally maintains a list of empty frames and a counter with the number of empty frames on the writer side of the pipe, and a list of full frames and a counter with the number of full frames on the reader side of the pipe. The pipe object also contains a descriptor of the current writer frame (that is, the last frame allocated and currently being filled by the application) and the current reader frame (that is, the last full frame that the application got and that is currently reading).

When PIP_alloc is called, the writer counter is decreased by one. An empty frame is removed from the writer list and the writer frame descriptor is updated with the information from this frame. When the application calls PIP_put after filling the frame, the reader counter is increased by one, and the writer frame descriptor is used by DSP/BIOS to add the new full frame to the pipe’s reader list.

**Note:**

Every call to PIP_alloc must be followed by a call to PIP_put before PIP_alloc can be called again: the pipe I/O mechanism does not allow consecutive PIP_alloc calls. Doing so would overwrite previous descriptor information and would produce undetermined results. This is shown in Example 6-3.
Similarly when PIP_get is called, the reader counter is decreased by one. A full frame is removed from the reader list and the reader frame descriptor is updated with the information from this frame. When the application calls PIP_free after reading the frame, the writer counter is increased by one, and the reader frame descriptor is used by DSP/BIOS to add the new empty frame to the pipe’s writer list. Hence, every call to PIP_get must be followed by a call to PIP_free before PIP_get can be called again as shown in Example 6-4.

The pipe I/O mechanism does not allow consecutive PIP_get calls. Doing so would overwrite previous descriptor information and produce undetermined results.

Example 6-4 Using PIP_get

```
/* correct */  /* error! */
PIP_get();     PIP_get();
...           ...
PIP_free();   PIP_get();
...           ...
PIP_get();   PIP_free();
...           ...
PIP_free(); PIP_free();
```

### 6.3.4.1 Avoiding Recursion Problems

Care should be applied when a pipe’s notify function calls PIP APIs for the same pipe.

Consider the following example: A pipe’s notifyReader function calls PIP_get for the same pipe. The pipe’s reader is an HWI routine. The pipe’s writer is an SWI routine. Hence the reader has higher priority than the writer. (Calling PIP_get from the notifyReader in this situation can make sense because this allows the application to get the next full buffer ready to be used by the reader—the HWI routine—as soon as it is available and before the hardware interrupt is triggered again.)
The pipe’s reader function, the HWI routine, calls PIP_get to read data from the pipe. The pipe’s writer function, the SWI routine, calls PIP_put. Since the call to the notifyReader happens within PIP_put in the context of the current routine, a call to PIP_get also happens from the SWI writer routine.

Hence, in the example described two threads with different priorities call PIP_get for the same pipe. This could have catastrophic consequences if one thread preempts the other and as a result, PIP_get is called twice before calling PIP_free, or PIP_get is preempted and called again for the same pipe from a different thread.

**Note:**
As a general rule to avoid recursion, you should avoid calling PIP functions as part of notifyReader and notifyWriter. If necessary for application efficiency, such calls should be protected to prevent reentrancy for the same pipe object and the wrong calling sequence for the PIP APIs.
6.4 Host Channel Manager (HST Module)

The HST module manages host channel objects, which allow an application to stream data between the target and the host. Host channels are configured for input or output. Input streams read data from the host to the target. Output streams transfer data from the target to the host.

**Note:**

HST channel names cannot start with a leading underscore (_).

You dynamically bind channels to files on the PC host by right-clicking on the Code Composer Studio Host Channel Control. Then you start the data transfer for each channel as shown in Example 6-4.

**Figure 6-4. Binding Channels**

Each host channel is internally implemented using a pipe object. To use a particular host channel, the program uses HST_getpipe to get the corresponding pipe object and then transfers data by calling the PIP_get and PIP_free operations (for input) or PIP_alloc and PIP_put operations (for output).

The code for reading data might look like Example 6-5.
Each host channel can specify a data notification function to be performed when a frame of data for an input channel (or free space for an output channel) is available. This function is triggered when the host writes or reads a frame of data.

HST channels treat files as 16- or 32-bit words of raw data, depending on the platform. The format of the data is application-specific, and you should verify that the host and the target agree on the data format and ordering. For example, if you are reading 32-bit integers from the host, you need to make sure the host file contains the data in the correct byte order. Other than correct byte order, there are no special format or data type requirements for data to be transferred between the host and the target.

While you are developing a program, you can use HST objects to simulate data flow and to test changes made to canned data by program algorithms. During early development, especially when testing signal processing algorithms, the program would explicitly use input channels to access data sets from a file for input for the algorithm and would use output channels to record algorithm output. The data saved to a file with the output host channel can be compared with expected results to detect algorithm errors. Later in the program development cycle, when the algorithm appears sound, you can change the HST objects to PIP objects communicating with other threads or I/O drivers for production hardware.
6.4.1 Transfer of HST Data to the Host

While the amount of usable bandwidth for real-time transfer of data streams to the host ultimately depends on the choice of physical data link, the HST Channel interface remains independent of the physical link. The HST Manager in the Configuration Tool allows you to choose among the physical connections available.

The actual data transfer to the host occurs within the idle loop on the C54x platform, running at lowest priority.

On the C55x and C6000 platforms, the host PC triggers an interrupt to transfer data to and from the target. This interrupt has a higher priority than SWI, TSK, and IDL functions. The actual ISR function runs in a very short time. Within the idle loop, the LNK_dataPump function does the more time-consuming work of preparing the RTDX buffers and performing the RTDX calls. Only the actual data transfer is done at high priority. This data transfer can have a small effect on real-time behavior, particularly if a large amount of LOG data must be transferred.

6.5 I/O Performance Issues

If you are using an HST object, the host PC reads or writes data using the function specified by the LNK_dataPump object. This is a built-in IDL object that runs its function as part of the background thread. Since background threads have the lowest priority, software interrupts and hardware interrupts can preempt data transfer on the C54x platform, whereas on the C55x and C6000 platforms, the actual data transfer occurs at high priority.

The polling rates you set in the LOG, STS, and TRC controls do not control the data transfer rate for HST objects. Faster polling rates actually slow the data transfer rate somewhat because LOG, STS, and TRC data also need to be transferred.
This chapter describes issues relating to writing and using device drivers, and gives several programming examples.
7.1 Overview of Streaming I/O and Device Drivers

Chapter 6 describes the device-independent I/O operations supported by DSP/BIOS from the vantage point of an application program. Programs indirectly invoke corresponding functions implemented by the driver managing the particular physical device attached to the stream, using generic functions provided by the SIO module. As depicted in the shaded portion of Figure 7-1, this chapter describes device-independent I/O in DSP/BIOS from the driver’s perspective of this interface.

Figure 7-1. Device-Independent I/O in DSP/BIOS

Unlike other modules, your application programs do not issue direct calls to driver functions that manipulate individual device objects managed by the SIO module. Instead, each driver module exports a specifically named structure of a specific type (DEV_Fxns), which in turn is used by the SIO module to route generic function calls to the proper driver function.

As illustrated in Table 7-1, each SIO operation calls the appropriate driver function by referencing this table. Dxx designates the device-specific function which you write for your particular device.
These internal driver functions can rely on virtually all of the capabilities supplied by DSP/BIOS, ranging from the multitasking features of the kernel to the application-level services. Drivers use the device-independent I/O interface of DSP/BIOS to communicate indirectly with other drivers, especially in supporting stackable devices.
Figure 7-2 illustrates the relationship between the device, the Dxx device driver, and the stream accepting data from the device. SIO calls the Dxx functions listed in DEV_Fxns, the function table for the device. Both input and output streams exchange buffers with the device using the atomic queues device→todevice and device→fromdevice.

For every device driver you need to write Dxx_open, Dxx_idle, Dxx_input, Dxx_output, Dxx_close, Dxx_ctrl, Dxx_ready, Dxx_issue, and Dxx_reclaim.
7.2 Creating and Deleting Streams

To enable your application to do streaming I/O with a device, the device must first be added with the Configuration Tool. You can add a device for any driver included in the product distribution or a user-supplied driver. To use a stream to perform I/O with a device, first configure the device in the Configuration Tool. Then, create the stream object in the Configuration Tool or at runtime with the SIO_create function.

7.2.1 Creating Streams with the Configuration Tool

You can create streams using the Configuration Tool. The Configuration Tool allows you to set the stream attributes for each stream and for the SIO Manager itself. You cannot use the SIO_delete function to delete streams created with the Configuration Tool.

7.2.2 Creating and Deleting Streams Dynamically

You can also create a stream at run time with the SIO_create function as shown in Example 7-1.

Example 7-1. Creating a Stream with SIO_create

```c
SIO_Handle SIO_create(name, mode, bufsize, attrs)
   String       name;
   Int          mode;
   Uns          bufsize;
   SIO_Attrs    *attrs;
```

SIO_create creates a stream and returns a handle of type SIO_Handle. SIO_create opens the device(s) specified by name, specifying buffers of size bufsize. Optional attributes specify the number of buffers, the buffer memory segment, the streaming model, etc. The mode parameter is used to specify whether the stream is an input (SIO_INPUT) or output (SIO_OUTPUT) stream.

**Note:**

The parameter name must match the name given to the device in the Configuration Tool preceded by a slash character (/). For example, for a device called sine, name should be "/sine."
Creating and Deleting Streams

If you open the stream with the streaming model (attrs→model) set to SIO_STANDARD (the default), buffers of the specified size are allocated and used to prime the stream. If you open the stream with the streaming model set to SIO_ISSUERECLAIM, no stream buffers are allocated, since the creator of the stream is expected to supply all necessary buffers.

SIO_delete, shown in Example 7-2, closes the associated device(s) and frees the stream object. If the stream was opened using the SIO_STANDARD streaming model, it also frees all buffers remaining in the stream. User-held stream buffers must be explicitly freed by the user’s code.

Example 7-2. Freeing User-Held Stream Buffers

```c
Int SIO_delete(stream)
    SIO_Handle    stream;
```
7.3 Stream I/O—Reading and Writing Streams

There are two models for streaming data in DSP/BIOS: the standard model and the Issue/Reclaim model. The standard model provides a simple method for using streams, while the Issue/Reclaim model provides more control over the stream operation.

SIO_get and SIO_put implement the standard stream model as shown in Example 7-3. SIO_get is used to input the data buffers. SIO_get exchanges buffers with the stream. The bufp parameter is used to pass the device a buffer and return a different buffer to the application. SIO_get returns the number of bytes in the input buffer. The SIO_put function performs the output of data buffers, and, like SIO_get, exchanges physical buffers with the stream. SIO_put takes the number of bytes in the output buffer.

Example 7-3. Inputting and Outputting Data Buffers

```c
Int SIO_get(stream, bufp)
SIO_Handle stream;
Ptr *bufp;

Int SIO_put(stream, bufp, nbytes)
SIO_Handle stream;
Ptr *bufp;
Uns nbytes;
```

Note:

Since the buffer pointed to by bufp is exchanged with the stream, the buffer size, memory segment, and alignment must correspond to the attributes of stream.

SIO_issue and SIO_reclaim are the calls that implement the Issue/Reclaim streaming model as shown in Example 7-4. SIO_issue sends a buffer to a stream. No buffer is returned, and the stream returns control to the task without blocking. arg is not interpreted by DSP/BIOS, but is offered as a service to the stream client. arg is passed to each device with the associated buffer data. It can be used by the stream client as a method of communicating with the device drivers. For example, arg could be used to send a time stamp to an output device, indicating exactly when the data is to be rendered. SIO_reclaim requests a stream to return a buffer.
Example 7-4. Implementing the Issue/Reclaim Streaming Model

If no buffer is available, the stream will block the task until the buffer becomes available or the stream's timeout has elapsed.

At a basic level, the most obvious difference between the standard and Issue/Reclaim models is that the Issue/Reclaim model separates the notification of a buffer's arrival (SIO_issue) and the waiting for a buffer to become available (SIO_reclaim). So, an SIO_issue/SIO_reclaim pair provides the same buffer exchange as calling SIO_get or SIO_put.

The Issue/Reclaim streaming model provides greater flexibility by allowing the stream client to control the number of outstanding buffers at runtime. A client can send multiple buffers to a stream, without blocking, by using SIO_issue. The buffers are returned, at the client's request, by calling SIO_reclaim. This allows the client to choose how deep to buffer a device and when to block and wait for a buffer.

The Issue/Reclaim streaming model also provides greater determinism in buffer management by guaranteeing that the client's buffers are returned in the order that they were issued. This allows a client to use memory from any source for streaming. For example, if a DSP/BIOS task receives a large buffer, that task can pass the buffer to the stream in small pieces—simply by advancing a pointer through the larger buffer and calling SIO_issue for each piece. This works because each piece of the buffer is guaranteed to come back in the same order it was sent.

7.3.1 Buffer Exchange

An important part of the streaming model in DSP/BIOS is buffer exchange. To provide efficient I/O operations with a low amount of overhead, DSP/BIOS avoids copying data from one place to another during certain I/O operations. Instead, DSP/BIOS uses SIO_get, SIO_put, SIO_issue, and SIO_reclaim to move buffer pointers to and from the device. Figure 7-3 shows a conceptual view of how SIO_get works.
In Figure 7-3, the device driver associated with stream fills a buffer as data becomes available. At the same time, the application program is processing the current buffer. When the application uses SIO_get to get the next buffer, the new buffer that was filled by the input device is swapped for the buffer passed in. This is accomplished by exchanging buffer pointers instead of copying bufsize bytes of data, which would be very time consuming. Therefore, the overhead of SIO_get is independent of the buffer size.

In each case, the actual physical buffer has been changed by SIO_get. The important implication is that you must make sure that any references to the buffer used in I/O are updated after each operation. Otherwise, you are referencing an invalid buffer.

SIO_put uses the same exchange of pointers to swap buffers for an output stream. SIO_issue and SIO_reclaim each move data in only one direction. Therefore, an SIO_issue/SIO_reclaim pair result in the same swapping of buffer pointers.

**Note:**

A single stream cannot be used by more than one task simultaneously. That is, only a single task can call SIO_get/SIO_put or SIO_issue/SIO_reclaim at once for each stream in your application.
7.3.2  Example - Reading Input Buffers from a DGN Device

The program in Example 7-5 illustrates some of the basic SIO functions and provides a straightforward example of reading from a stream. For a complete description of the DGN software generator driver, see the DGN section in the TMS320 DSP/BIOS API Reference Guide for your platform.

The configuration template for Example 7-5 can be found in the siotest directory of the DSP/BIOS distribution. A DGN device called sineWave is used as a data generator to the SIO stream inputStream. The task streamTask calls the function doStreaming to read the sine data from the inputStream and prints it to the log buffer trace. The output for Example 7-5 appears as sine wave data in Figure 7-4.

Example 7-5.  Basic SIO Functions

```c
/*
* ======== siotest1.c ========
* In this program a task reads data from a DGN sine device
* and prints the contents of the data buffers to a log buffer.
* The data exchange between the task and the device is done
* in a device independent fashion using the SIO module APIs.
* The stream in this example follows the SIO_STANDARD streaming
* model and is created using the Configuration Tool.
*/

#include <std.h>
#include <log.h>
#include <sio.h>
#include <sys.h>
#include <tsk.h>

extern Int IDRAM1; /* MEM segment ID defined by Conf tool */
extern LOG_Obj trace; /* LOG object created with Conf tool */
extern SIO_Obj inputStream; /* SIO object created w Conf tool */
extern TSK_Obj streamTask; /* pre-created task */

SIO_Handle input = &inputStream; /* SIO handle used below */

Void doStreaming(Uns nloops); /* function for streamTask */

/*
* ======== main ========
*/

Void main()
{
    LOG_printf(&trace, "Start SIO example #1");
}
/*
Example 7.5. Basic SIO Function (continued)

```c
* ======== doStreaming ========
* This function is the body of the pre-created TSK thread
* streamTask.
* /
Void doStreaming(Uns nloops)
{
    Int i, j, nbytes;
    Int *buf;
    status = SIO_staticbuf(input, (Ptr *)&buf);
    if (status != SYS_ok) {
        SYS_abort("could not acquire static frame:");
    }

    for (i = 0; i < nloops; i++) {
        if ((nbytes = SIO_get(input, (Ptr *)&buf)) < 0) {
            SYS_abort("Error reading buffer %d", i);
        }

        LOG_printf(&trace, "Read %d bytes
Buffer %d data:",
            nbytes, i);
        for (j = 0; j < nbytes / sizeof(Int); j++) {
            LOG_printf(&trace, "%d", buf[j]);
        }
    }

    LOG_printf(&trace, "End SIO example #1");
}
```
7.3.3 Example - Reading and Writing to a DGN Device

Example 7-6 adds new SIO operations to the previous one. An output stream, outputStream, has been added with the Configuration Tool. streamTask reads buffers from a DGN sine device as before, but now it sends the data buffers to outputStream rather than printing the contents to a log buffer. The stream outputStream sends the data to a DGN user device called printData. Device printData takes the data buffers received and uses the DGN_print2log function to display their contents in a log buffer. The log buffer is specified by the user in the Configuration Tool.
Example 7-6. Adding an Output Stream to Example 7-5

```c
====== Portion of siotest2.c ======
/* SIO objects created with conf tool */
extern far LOG_Obj trace;
extern far SIO_Obj inputStream;
extern far SIO_Obj outputStream;
extern far TSK_Obj streamTask;
SIO_Handle input = &inputStream;
SIO_Handle output = &outputStream;
...

Void doStreaming(Uns nloops)
{
    Void doStreaming(Arg nloops_arg)
    {
        Int i, nbytes;
        Int *buf;
        Long nloops = (Long) nloops_arg;
        if ( SIO_staticbuf(input, (Ptr *)&buf) == 0) {
            SYS_abort("Error reading buffer ");
        }
        for (i = 0; i < nloops; i++) {
            if ((nbytes = SIO_get(input, (Ptr *)&buf)) < 0) {
                SYS_abort("Error reading buffer %d", (Arg)i);
            }
            if (SIO_put(output, (Ptr *)&buf, nbytes) < 0) {
                SYS_abort("Error writing buffer %d", (Arg)i);
            }
        }
        LOG_printf(&trace, "End SIO example #2");
    }

    /* User function for the DGN user device printData. It takes as an argument
     * the address of the LOG object where the data stream should be printed. */
    Void DGN_print2log(Arg arg, Ptr addr, Uns nbytes)
    {
        Int i;
        Int *buf;
        buf = (Int *)addr;
        for (i = 0; i < nbytes/sizeof(Int); i++) {
            LOG_printf((LOG_Obj *)arg, "%d", buf[i]);
        }
    }
```

Note:
Non-pointer type function arguments to log_printf need explicit type casting to (Arg) as shown in the following code example:

```c
LOG_printf(&trace, "Task %d Done", (Arg)id);
```
Stream I/O—Reading and Writing Streams

The complete source code and configuration template for Example 7-6 can be found in the c:\ti\tutorial\target\siotest directory of the DSP/BIOS product distribution (siotest2.c, siotest2.cdb, dgn_print.c). For more details on how to add and configure a DGN device using the Configuration Tool, see the DGN section in the TMS320 DSP/BIOS API Reference Guide for your platform.

In the output for this example, sine wave data appears in the myLog window display.

7.3.4 Example - Stream I/O using the Issue/Reclaim Model

Example 7-7 is functionally equivalent to Example 7-6. However, the streams are now created using the Issue/Reclaim model, and the SIO operations to read and write data to a stream are SIOIssue and SIO_reclaim.

In this model, when streams are created dynamically, no buffers are initially allocated so the application must allocate the necessary buffers and provide them to the streams to be used for data I/O. For static streams, you can allocate static buffers with the Configuration Tool by checking the Allocate Static Buffer(s) check box for the SIO object.
Example 7-7. Using the Issue/Reclaim Model

```c
/* ======= doIRstreaming ======== */
Void doIRstreaming(Uns nloops)
{
    Ptr    buf;
    Arg    arg;
    Int    i, nbytes;

    /* Prime the stream with a couple of buffers */
    buf = MEM_alloc(IDRAM1, SIO_bufsize(input), 0);
    if (buf == MEM_ILLEGAL) {
        SYS_abort("Memory allocation error");
    }
    /* Issue an empty buffer to the input stream */
    if (SIO_issue(input, buf, SIO_bufsize(input), NULL) < 0) {
        SYS_abort("Error issuing buffer %d", i);
    }
    buf = MEM_alloc(IDRAM1, SIO_bufsize(input), 0);
    if (buf == MEM_ILLEGAL) {
        SYS_abort("Memory allocation error");
    }
    for (i = 0; i < nloops; i++) {
        /* Issue an empty buffer to the input stream */
        if (SIO_issue(input, buf, SIO_bufsize(input), NULL) < 0) {
            SYS_abort("Error issuing buffer %d", i);
        }
        /* Reclaim full buffer from the input stream */
        if ((nbytes = SIO_reclaim(input, &buf, &arg)) < 0) {
            SYS_abort("Error reclaiming buffer %d", i);
        }
        /* Issue full buffer to the output stream */
        if (SIO_issue(output, buf, nbytes, NULL) < 0) {
            SYS_abort("Error issuing buffer %d", i);
        }
        /* Reclaim empty buffer from the output stream to be reused */
        if (SIO_reclaim(output, &buf, &arg) < 0) {
            SYS_abort("Error reclaiming buffer %d", i);
        }
    }
    /* Reclaim and delete the buffers used */
    MEM_free(IDRAM1, buf, SIO_bufsize(input));
    if ((nbytes = SIO_reclaim(input, &buf, &arg)) < 0) {
        SYS_abort("Error reclaiming buffer %d", i);
    }
    if (SIO_issue(output, buf, nbytes, NULL) < 0) {
        SYS_abort("Error issuing buffer %d", i);
    }
    if (SIO_reclaim(output, &buf, &arg) < 0) {
        SYS_abort("Error reclaiming buffer %d", i);
    }
    MEM_free(IDRAM1, buf, SIO_bufsize(input));
}
```

The complete source code and configuration template for this example can be found in the C:\tutorial\target\siotest folder of the DSP/BIOS product, where target represents your platform. The output for Example 7-7 is the same as found in Example 7-5.
7.4 Stackable Devices

The capabilities of the SIO module play an important role in fostering device-independence within DSP/BIOS in that logical devices insulate your application programs from the details of designating a particular device. For example, /dac is a logical device name that does not imply any particular DAC hardware. The device-naming convention adds another dimension to device-independent I/O that is unique to DSP/BIOS—the ability to use a single name to denote a stack of devices.

**Note:**

By stacking certain data streaming or message passing devices atop one another, you can create virtual I/O devices that further insulate your applications from the underlying system hardware.

Consider, as an example, a program implementing an algorithm that inputs and outputs a stream of fixed-point data using a pair of A/D-D/A converters. However, the A/D-D/A device can take only the 14 most significant bits of data, and the other two bits have to be 0 if you want to scale up the input data.

Instead of cluttering the program with excess code for data conversion and buffering to satisfy the algorithm's needs, we can open a pair of virtual devices that implicitly perform a series of transformations on the data produced and consumed by the underlying real devices as shown in Example 7-8.

**Example 7-8. Opening a Pair of Virtual Devices**

```c
SIO_Handle input;
SIO_Handle output;
Ptr        buf;
Int        n;
buf = MEM_alloc(0, MAXSIZE, 0);
input = SIO_create("/scale2/a2d", SIO_INPUT, MAXSIZE, NULL);
output = SIO_create("/mask2/d2a", SIO_OUTPUT, MAXSIZE, NULL);
while (n = SIO_get(input, &buf)) {
    `apply algorithm to contents of buf`
    SIO_put(output, &buf, n);
}
SIO_delete(input);
SIO_delete(output);
```
In Example 7-8, the virtual input device, /scale2/a2d, actually comprises a stack of two devices, each named according to the prefix of the device name specified in your configuration file.

- /scale2 designates a device that transforms a fixed-point data stream produced by an underlying device (/a2d) into a stream of scaled fixed-point values; and
- /a2d designates a device managed by the A/D-D/A device driver that produces a stream of fixed-point input from an A/D converter.

The virtual output device, /mask2/d2a, likewise denotes a stack of two devices. Figure 7-6 shows the flow of empty and full frames through these virtual source and sink devices as the application program calls the SIO data streaming functions.

Figure 7-6. The Flow of Empty and Full Frames

7.4.1 Example - SIO_create and Stacking Devices.

Example 7-9, illustrates two tasks, sourceTask and sinkTask, that exchange data through a pipe device.

sourceTask is a writer task that receives data from an input stream attached to a DGN sine device and redirects the data to an output stream attached to a DPI pipe device. The input stream also has a stacking device, scale, on top of the DGN sine device. The data stream coming from sine is first processed by the scale device (that multiplies each data point by a constant integer value), before it is received by sourceTask.

sinkTask is a reader task that reads the data that sourceTask sent to the DPI pipe device through an input stream, and redirects it to a DGN printData device through an output stream.
The devices in Example 7-9 have been configured with the Configuration Tool. The complete source code and configuration template for Example 7-9 can be found in the c:\ti\tutorial\target\siotest directory of the DSP/BIOS product distribution (siotest5.c, siotest5.cdb, dgn_print.c). The devices sineWave and printDat are DGN devices. pip0 is a DPI device. scale is a DTR stacking device. For more information on how to add and configure DPI, DGN, and DTR devices, see the DPI, DGN and DTR drivers description in the TMS320 DSP/BIOS API Reference Guide for your platform.

The streams in Example 7-9 have also been added using the Configuration Tool. The input stream for the sourceTask task is inStreamSrc and has been configured as shown in Figure 7-7.

Figure 7-7. inStreamSrc Properties Dialog Box
When you add an SIO stream in the Configuration Tool that uses a stacking device, you must first enter a configured terminal device in the Device Control Parameter property box. The name of the terminal device must be preceded by a slash character (/). In the example we use /sineWave, where sineWave is the name of a configured DGN terminal device. Then select the stacking device (scale) from the dropdown list in the Device property. The Configuration Tool will not allow you to select a stacking device in Device until a terminal device has been entered in Device Control Parameter. The other SIO streams created for Example 7-9 are outStreamSrc (output stream for sourceTask), inStreamSink (input stream for sinkTask), and outStreamSink (output stream for sinkTask). The devices used by these streams are the terminal devices pip0 and printData.
Example 7-9. Data Exchange Through a Pipe Device

```c
/*
 *  ======== siotest5.c ========
 *  In this program two tasks are created that exchange data
 *  through a pipe device. The source task reads sine wave data
 *  from a DGN device through a DTR device stacked on the sine
 *  device, and then writes it to a pipe device. The sink task
 *  reads the data from the pipe device and writes it to the
 *  printData DGN device. The data exchange between the tasks
 *  and the devices is done in a device independent fashion
 *  using the SIO module APIs.
 *  The streams in this example follow the SIO_STANDARD streaming
 *  model and are created with the Configuration Tool.
 */
#include <std.h>

*/
static Void doStreaming(SIO_Handle input, SIO_Handle output, Uns nloops)
{
    Ptr    buf;
    Int    i, nbytes;
    if (SIO_staticbuf(input, &buf) == 0){
        SYS_abort("Error reading buffer \d", i);
    }
    for (i = 0; i < nloops; i++) {
        if (SIO_get(input, &buf) <0) {
            SYS_abort ("Error reading buffer \d", i);
        }
        if (SIO_put(output, &buf, nbytes) <0) {
            SYS_abort ("Error writing buffer \d", i);
        }
    }
}
```

In the output for Example 7-9, scaled sine wave data appears in the myLog window display in Example 7-8.
You can edit `sioTest5.c` and change the scaling factor of the DTR_PRMS, rebuild the executable and see the differences in the output to `myLog`.

A version of Example 7-9, where the streams are created dynamically at runtime by calling SIO_create is available in the product distribution (siotest4.c, siotest4.cdb).
7.5 Controlling Streams

A physical device typically requires one or more specialized control signals in order to operate as desired. SIO_ctrl makes it possible to communicate with the device, passing it commands and arguments. Since each device admits only specialized commands, you need to consult the documentation for each particular device. The general calling format is shown in Example 7-10.

Example 7-10. Using SIO_ctrl to Communicate with a Device

```c
Int SIO_ctrl(stream, cmd, arg)
SIO_Handle stream;
Uns    cmd;
Ptr    arg;
```

The device associated with stream is passed the command represented by the device-specific cmd. A generic pointer to the command’s arguments is also passed to the device. The actual control function that is part of the device driver then interprets the command and arguments and acts accordingly.

Assume that an analog-to-digital converter device /a2d has a control operation to change the sample rate. The sample rate might be changed to 12 kHz as shown in Example 7-11.

Example 7-11. Changing Sample Rate

```c
SIO_Handle     stream;
stream = SIO_create("/a2d", ...);
SIO_ctrl(stream, DAC_RATE, 12000);
```

In some situations, you can synchronize with an I/O device that is doing buffered I/O. There are two methods to synchronize with the devices: SIO_idle and SIO_flush. Either function leaves the device in the idled state. Idling a device means that all buffers are returned to the queues that they were in when the device was initially created. That is, the device is returned to its initial state, and streaming is stopped.

For an input stream, the two functions have the same results: all unread input is lost. For an output stream, SIO_idle blocks until all buffered data has been written to the device. However, SIO_flush discards any data that has not already been written. SIO_flush does not block as shown in Example 7-12.

Example 7-12. Synchronizing with a Device

```c
Void SIO_idle(stream);
SIO_Handle     stream;
Void SIO_flush(stream);
SIO_Handle     stream;
```

An idle stream does not perform I/O with its underlying device. Thus, a stream can be turned off until further input or output is needed by calling SIO_idle or SIO_flush.
The SIO_select function allows a single DSP/BIOS task to wait until an I/O operation can be performed on one or more of a set of SIO streams without blocking. For example, this mechanism is useful in the following applications:

- **Non-blocking I/O.** Real-time tasks that stream data to a slow device (for example, a disk file) must ensure that SIO_put does not block.

- **Multitasking.** In virtually any multitasking application there are daemon tasks that route data from several sources. The SIO_select mechanism allows a single task to handle all of these sources.

SIO_select is called with an array of streams, an array length, and a time-out value. SIO_select blocks (if timeout is not 0) until one of the streams is ready for I/O or the time-out expires. In either case, the mask returned by SIO_select indicates which devices are ready for service (a 1 in bit j indicates that streamtab[j] is ready) as shown in Example 7-13.

**Example 7-13. Indicating That a Stream is Ready**

```c
Uns SIO_select(streamtab, nstreams, timeout)
SIO_Handle streamtab[]; /* stream table */
Uns nstreams; /* number of streams */
Uns timeout; /* return after this many */
/* system clock ticks */
```

**7.6.1 Programming Example**

In Example 7-14, two streams are polled to see if an I/O operation will block.

**Example 7-14. Polling Two Streams**

```c
SIO_Handle stream0;
SIO_Handle stream1;
SIO_Handle streamtab[2];
Uns mask;
...
streamtab[0] = stream0;
streamtab[1] = stream1;
while ((mask = SIO_select(streamtab, 2, 0)) == 0) {
    'I/O would block, do something else'
}
if (mask & 0x1) {
    'service stream0'
}
if (mask & 0x2) {
    'service stream1'
}
```
7.7 Streaming Data to Multiple Clients

A common problem in multiprocessing systems is the simultaneous transmission of a single data buffer to multiple tasks in the system. Such multi-cast transmission, or scattering of data, can be done easily with DSP/BIOS SIO streams. Consider the situation in which a single processor sends data to four client processors.

Streaming data between processors in this context is somewhat different from streaming data to or from an acquisition device, such as an A/D converter, in that a single buffer of data must go to one or more clients. The DSP/BIOS SIO functions SIO_get/SIO_put are used for data I/O.

SIO_put automatically performs a buffer exchange between the buffer already at the device level and the application buffer. As a result, the user no longer has control over the buffer since it is enqueued for I/O, and this I/O happens asynchronously at the interrupt level. This forces the user to copy data in order to send it to multiple clients. This is shown in Example 7-15.

**Example 7-15. Using SIO_put to Send Data to Multiple Clients**

```c
SIO_put(inStream, (Ptr)&bufA, npoints);

'fill bufA with data'
for ('all data points') {
    bufB[i] = bufC[i] = bufD[i] ... = bufA[i];
}
SIO_put(outStreamA, (Ptr)&bufA, npoints);
SIO_put(outStreamB, (Ptr)&bufB, npoints);
SIO_put(outStreamC, (Ptr)&bufC, npoints);
SIO_put(outStreamD, (Ptr)&bufD, npoints);
```

Copying the data wastes CPU cycles and requires more memory, since each stream needs buffers. If you were double-buffering, Example 7-15 would require eight buffers (two for each stream).

Example 7-16, illustrates the advantage of SIO_issue and SIO_reclaim in this situation. The application performs no copying, and it uses only two buffers. In each call, SIO_issue simply enqueues the buffer pointed to by bufA onto outStream’s todevice queue without blocking. Since there is no copying or blocking, this method greatly reduces the time between having a buffer of data ready for transmission and the time the buffer can be sent to all clients. In order to remove the buffers from the output devices, corresponding SIO_reclaim functions must be called.
Streaming Data to Multiple Clients

Example 7-16. Using SIO_issue/SIO_reclaim to Send Data to Multiple Clients

```c
SIO_issue(outStreamA, (Ptr)bufA, npoints, NULL);
SIO_issue(outStreamB, (Ptr)bufA, npoints, NULL);
SIO_issue(outStreamC, (Ptr)bufA, npoints, NULL);
SIO_issue(outStreamD, (Ptr)bufA, npoints, NULL);
SIO_reclaim(outStreamA, (Ptr)&bufA, NULL);
SIO_reclaim(outStreamB, (Ptr)&bufA, NULL);
SIO_reclaim(outStreamC, (Ptr)&bufA, NULL);
SIO_reclaim(outStreamD, (Ptr)&bufA, NULL, SYS_FOREVER);
```

Note:

Using SIO_issue to send the same buffer to multiple devices does not work with device drivers that modify the data in the buffer, since the buffer is simultaneously being sent to multiple devices. For example, a stacking device that transforms packed data to unpacked data is modifying the buffer at the same time that another device is outputting the buffer.

The SIO_issue interface provides a method for allowing all communications drivers access to the same buffer of data. Each communications device driver, which typically uses DMA transfers, then transfers this buffer of data concurrently. The program does not return from the four SIO_reclaims until a buffer is available from all of the streams.

In summary, the SIO_issue/SIO_reclaim functions offer the most efficient method for the simultaneous transmission of data to more than one stream. This is not a reciprocal operation: the SIO_issue/SIO_reclaim model solves the scatter problem quite efficiently for output, but does not accommodate gathering multiple data sources into a single buffer for input.
7.8 Streaming Data Between Target and Host

Using the Configuration Tool, you can create host channel objects (HST objects), which allow an application to stream data between the target and files on the host. In DSP/BIOS Analysis Tools, you bind these channels to host files and start them.

DSP/BIOS includes a host I/O module (HST) that makes it easy to transfer data between the host computer and target program. Each host channel is internally implemented using an SIO stream object. To use a host channel, the program calls HST_getstream to get the corresponding stream handle, and then transfers the data using SIO calls on the stream.

You configure host channels, or HST objects, for input or output using the Configuration Tool. Input channels transfer data from the host to the target, and output channels transfer data from the target to the host.
7.9 Device Driver Template

Since device drivers interact directly with hardware, the low-level details of device drivers can vary considerably. However, all device drivers must present the same interface to SIO. In the following sections, an example driver template called Dxx is presented. The template contains (mainly) C code for higher-level operations and pseudocode for lower-level operations. Any device driver should adhere to the standard behavior indicated for the Dxx functions.

You should study the Dxx driver template along with one or more actual drivers. You can also refer to the Dxx functions in the TMS320 DSP/BIOS API Reference Guide for your platform where xx denotes any two-letter combination. For details about configuring device drivers, including both custom drivers and the drivers provided with DSP/BIOS, you need to reference the specific device driver.

7.9.1 Typical File Organization

Device drivers are usually split into multiple files. For example:

- dxx.h—Dxx header file
- dxx.c—Dxx functions
- dxx_asm.s##—(optional) assembly language functions

Most of the device driver code can be written in C. The following description of Dxx does not use assembly language. However, interrupt service routines are usually written in assembly language for efficiency, and some hardware control functions also need to be written in assembly language.

We recommend that you become familiar at this point with the layout of one of the software device drivers, such as DGN. In particular, you should note the following points:

- The header file, dxx.h, typically contains the required statements shown in Example 7-17 in addition to any device-specific definitions:
Example 7-17. Required Statements in dxx.h Header File

```c
/*
 * ======= dxx.h =======
*/

#include <dev.h>
extern DEV_Fxns Dxx_FXNS;

/*@*/
/*
 * ======== Dxx_Params ========
*/
typedef struct {
    /* device parameters go here */
} Dxx_Params;

Device parameters, such as Dxx_Params, are specified as properties of the device object in the Configuration Tool.

The required table of device functions is contained in dxx.c. This table is used by the SIO module to call specific device driver functions. For example, SIO_put uses this table to find and call Dxx_issue/Dxx_reclaim. The table is shown in Example 7-18.

Example 7-18. Table of Device Functions

```
DEV_Fxns Dxx_FXNS = {
    Dxx_close,
    Dxx_ctrl,
    Dxx_idle,
    Dxx_issue,
    Dxx_open,
    Dxx_ready,
    Dxx_reclaim
};
```
7.10 Streaming DEV Structures

The DEV_Fxns structure contains pointers to internal driver functions corresponding to generic I/O operations as shown in Example 7-19.

Example 7-19. The DEV_Fxns Structure

```c
typedef struct DEV_Fxns {
    Int (*close)(DEV_Handle);
    Int (*ctrl)(DEV_Handle, Uns, Arg);
    Int (*idle)(DEV_Handle, Bool);
    Int (*issue)(DEV_Handle);
    Int (*open)(DEV_Handle, String);
    Bool (*ready)(DEV_Handle, SEM_Handle);
    Int (*reclaim)(DEV_Handle);
} DEV_Fxns;
```

Device frames are structures of type DEV_Frame used by SIO and device drivers to enqueue/dequeue stream buffers as shown in Example 7-20. The device→todevice and device→fromdevice queues contain elements of this type.

Example 7-20. The DEV_Frame Structure

```c
typedef struct DEV_Frame {
    QUE_Elem link;
    Ptr addr;
    Uns size;
    Arg misc;
    Arg arg;
} DEV_Frame;
```

Example 7-20 has the following parameters:

- `link` is used by QUE_put and QUE_get to enqueue/dequeue the frame.
- `addr` contains the address of the stream buffer.
- `size` contains the logical size of the stream buffer. The logical size can be less than the physical buffer size.
- `misc` is an extra field which is reserved for use by a device.
- `arg` is an extra field available for you to associate information with a particular frame of data. This field should be preserved by the device.
Device driver functions take a DEV_Handle as their first or only parameter, followed by any additional parameters. The DEV_Handle is a pointer to a DEV_Obj, which is created and initialized by SIO_create and passed to Dxx_open for additional initialization. Among other things, a DEV_Obj contains pointers to the buffer queues that SIO and the device use to exchange buffers. All driver functions take a DEV_Handle as their first parameter.

Example 7-21. The DEV_Handle Structure

```c
typedef DEV_Obj *DEV_Handle;
typedef struct DEV_Obj {
    QUE_Handle todevice;
    QUE_Handle fromdevice;
    Uns        bufsize;
    Uns        nbufs;
    Int        segid;
    Int        mode;
    Int        devid;
    Ptr        params;
    Ptr        object;
    DEV_Fxns   fxns;
    Uns        timeout;
} DEV_Obj;
```

Example 7-21 has the following parameters:

- **todevice** is used to transfer DEV_Frame frames to the device. In the SIO_STANDARD (DEV_STANDARD) streaming model, SIO_put puts full frames on this queue, and SIO_get puts empty frames here. In the SIO_ISSUERECLAIM (DEV_ISSUERECLAIM) streaming model, SIO_issue places frames on this queue.

- **fromdevice** is used to transfer DEV_Frame frames from the device. In the SIO_STANDARD (DEV_STANDARD) streaming model, SIO_put gets empty frames from this queue, and SIO_get gets full frames from here. In the SIO_ISSUERECLAIM (DEV_ISSUERECLAIM) streaming model, SIO_reclaim retrieves frames from this queue.

- **bufsize** specifies the physical size of the buffers in the device queues.

- **nbufs** specifies the number of buffers allocated for this device in the SIO_STANDARD streaming model, or the maximum number of outstanding buffers in the SIO_ISSUERECLAIM streaming model.

- **segid** specifies the segment from which device buffers were allocated (SIO_STANDARD).

- **mode** specifies whether the device is an input (DEV_INPUT) or output (DEV_OUTPUT) device.
Streaming DEV Structures

- **devid** is the device ID.
- **params** is a generic pointer to any device-specific parameters. Some devices have additional parameters which are found here.
- **object** is a pointer to the device object. Most devices create an object that is referenced in successive device operations.
- **fxns** is a DEV_Fxns structure containing the driver’s functions. This structure is usually a copy of Dxx_FXNS, but it is possible for a driver to dynamically alter these functions in Dxx_open.
- **timeout** specifies the number of system ticks that SIO_reclaim will wait for I/O to complete.

Only the object and fxns fields should ever be modified by a driver’s functions. These fields are essentially output parameters of Dxx_open.
7.11 Device Driver Initialization

The driver function table Dxx_FXNS is initialized in dxx.c, as shown in section 7.10, Streaming DEV Structures, page 7-30.

Additional initialization is performed by Dxx_init. The Dxx module is initialized when other application-level modules are initialized. Dxx_init typically calls hardware initialization routines and initializes static driver structures as shown in Example 7-22.

Example 7-22. Initialization by Dxx_init

```c
/*
 *  ======== Dxx_init ========
 */

Void Dxx_init()
{
    /*Perform hardware initialization*/
}
```

Although Dxx_init is required in order to maintain consistency with DSP/BIOS configuration and initialization standards, there are actually no DSP/BIOS requirements for the internal operation of Dxx_init. There is in fact no standard for hardware initialization, and it can be more appropriate on some systems to perform certain hardware setup operations elsewhere in Dxx, such as Dxx_open. Therefore, on some systems, Dxx_init might simply be an empty function.
7.12 Opening Devices

Dxx_open opens a Dxx device and returns its status seen in Example 7-23:

Example 7-23. Opening a Device with Dxx_open

```c
status = Dxx_open(device, name);
```

SIO_create calls Dxx_open to open a Dxx device as seen in Example 7-24.

Example 7-24. Opening an Input Terminating Device

```c
input = SIO_create("/adc16", SIO_INPUT, BUFSIZE, NULL)
```

This sequence of steps illustrates the opening process for an input-terminating device:

1) Find string matching a prefix of /adc16 in DEV_devtab device table. The associated DEV_Device structure contains driver function, device ID, and device parameters.

2) Allocate DEV_Obj device object.

3) Assign bufsize, nbufs, segid, etc. fields in DEV_Obj from parameters and SIO_Attr passed to SIO_create.

4) Create todevice and fromdevice queues.

5) If opened for DEV_STANDARD streaming model, allocate attrs.nbufs buffers of size BUFSIZE and put them on todevice queue.

6) Call Dxx_open with pointer to new DEV_Obj and remaining name string using syntax as shown:

```c
status = Dxx_open (device, "16")
```

7) Validate fields in DEV_Obj pointed to by device.

8) Parse string for additional parameters (for example, 16 kHz).

9) Allocate and initialize device-specific object.

10) Assign device-specific object to device→object.

The arguments to Dxx_open are shown in Example 7-25.

Example 7-25. Arguments to Dxx_open

```c
DEV_Handle device; /* driver handle */
String name; /* device name */
```
The device parameter points to an object of type DEV_Obj whose fields have been initialized by SIO_create. name is the string remaining after the device name has been matched by SIO_create using DEV_match.

Recall that SIO_create takes the parameters and is called as shown in Example 7-26.

**Example 7-26. The Parameters of SIO_create**

```
stream = SIO_create(name, mode, bufsize, attrs);
```

The name parameter passed to SIO_create is typically a string indicating the device and an additional suffix, indicating some particular mode of operation of the device. An analog-to-digital converter might have the base name /adc, while the sampling frequency might be indicated by a tag such as 16 for 16 kHz. The complete name passed to SIO_create would be /adc16.

SIO_create identifies the device by using DEV_match to match the string /adc against the list of configured devices. The string remainder 16 would be passed to Dxx_open to set the ADC to the correct sampling frequency.

Dxx_open usually allocates a device-specific object that is used to maintain the device state, as well as necessary semaphores. For a terminating device, this object typically has two SEM_Handle semaphore handles. One is used for synchronizing I/O operations (for example, SIO_get, SIO_put, SIO_reclaim). The other handle is used with SIO_select to determine if a device is ready. A device object would typically be defined as shown in Example 7-27.

**Example 7-27. The Dxx_Obj Structure**

```
typedef struct Dxx_Obj {
    SEM_Handle sync;  /* synchronize I/O */
    SEM_Handle ready; /* used with SIO_select() */
    /* other device-specific fields */
} Dxx_obj, *Dxx_Handle;
```

Example 7-28 provides a template for Dxx_open, showing the function’s typical features for a terminating device.
Example 7-28. Typical Features for a Terminating Device

```c
Int Dxx_open(DEV_Handle device, String name)
{
    Dxx_Handle objptr;
    /* check mode of device to be opened */
    if ( device->mode is invalid ) {
        return (SYS_EMODE);
    }
    /* check device id */
    if ( device->devid is invalid ) {
        return (SYS_ENODEV);
    }
    /* if device is already open, return error */
    if ( device is in use ) {
        return (SYS_EBUSY);
    }
    /* allocate device-specific object */
    objptr = MEM_alloc(0, sizeof (Dxx_Obj), 0);
    /* fill in device-specific fields */
    /* create synchronization semaphore ... */
    objptr->sync = SEM_create( 0 , NULL);
    /* initialize ready semaphore for SIO_select() */
    Dxx_ready() */
    objptr->ready = NULL;
    /* do any other device-specific initialization required */
    /* assign initialized object */
    device->object = (Ptr)objptr;
    return (SYS_OK);
}
```

The first two steps take care of error checking. For example, a request to open an output-only device for input should generate an error message. A request to open channel ten on a five-channel system should also generate an error message.

The next step is to determine if the device is already opened. In many cases, an opened device cannot be re-opened, so a request to do so generates an error message.

If the device can be opened, the rest of Dxx_open consists of two major operations. First, the device-specific object is initialized, based in part on the device->params settings passed by SIO_create. Second, this object is attached to device->object. Dxx_open returns SYS_OK to SIO_create, which now has a properly initialized device object.
The configurable device parameters are used to set the operating parameters of the hardware. There are no DSP/BIOS constraints on which parameters should be set in Dxx_init rather than in Dxx_open.

The object semaphore objptr→sync is typically used to signal a task that is pending on the completion of an I/O operation. For example, a task can call SIO_put, which can block by pending on objptr→sync. When the required output is accomplished, SEM_post is called with objptr→sync. This makes a task blocked in Dxx_output ready to run.

DSP/BIOS does not impose any special constraints on the use of synchronization semaphores within a device driver. The appropriate use of such semaphores depends on the nature of the driver requirements and the underlying hardware.

The ready semaphore, objptr→ready, is used by Dxx_ready, which is called by SIO_select to determine if a device is available for I/O. This semaphore is explained in section 4.6, Semaphores, page 4-49.
7.13 Real-Time I/O

In DSP/BIOS there are two models that can be used for real-time I/O—the DEV_STANDARD streaming model and the DEV_ISSUERECLAIM streaming model. Each of these models is described in this section.

7.13.1 DEV_STANDARD Streaming Model

In the DEV_STANDARD streaming model, SIO_get is used to get a non-empty buffer from an input stream. To accomplish this, SIO_get first places an empty frame on the device->todevice queue. SIO_get then calls Dxx_issue, which starts the I/O and then calls Dxx_reclaim pending, until a full frame is available on the device->fromdevice queue. This blocking is accomplished by calling SEM_pend on the device semaphore objptr->sync that is posted whenever a buffer is filled.

Dxx_issue calls a low-level hardware function to initiate data input. When the required amount of data has been received, the frame is transferred to device->fromdevice. Typically, the hardware device triggers an interrupt when a certain amount of data has been received. Dxx handles this interrupt by means of an HWI (ISR in Figure 7-9), which accumulates the data and determine if more data is needed for the waiting frame. If the HWI determines that the required amount of data has been received, the HWI transfers the frame to device->fromdevice and then call SEM_post on the device semaphore. This allows the task, blocked in Dxx_reclaim, to continue. Dxx_reclaim then returns to SIO_get, which will complete the input operation as illustrated in Figure 7-9.

Figure 7-9. Flow of DEV_STANDARD Streaming Model
Note that objptr->sync is a counting semaphore and that tasks do not always block here. The value of objptr->sync represents the number of available frames on the fromdevice queue.

### 7.13.2 DEV_ISSUERECLAIM Streaming Model

In the DEV_ISSUERECLAIM streaming model, SIO_issue is used to send buffers to a stream. To accomplish this, SIO_issue first places the frame on the device->todevice queue. It then calls Dxx_issue which starts the I/O and returns.

Dxx_issue calls a low-level hardware function to initialize I/O.

SIO_reclaim is used to retrieve buffers from the stream. This is done by calling Dxx_reclaim, which blocks until a frame is available on the device->fromdevice queue. This blocking is accomplished by calling SEM_pend on the device semaphore objptr->sync, just as for Dxx_issue. When the device HWI (ISR in Figure 7-10 and Figure 7-11) posts to objptr->sync, Dxx_reclaim is unblocked, and returns to SIO_reclaim. SIO_reclaim then gets the frame from the device->fromdevice queue and returns the buffer. This sequence is shown in Figure 7-10 and Figure 7-11.

**Figure 7-10. Placing a Data Buffer to a Stream**

<table>
<thead>
<tr>
<th>Application</th>
<th>SIO_module</th>
<th>Dxx_module</th>
</tr>
</thead>
<tbody>
<tr>
<td>SIO_issue(outstream,bufp,nbytes,arg)</td>
<td>1) Put full bufp on todevice queue</td>
<td>1) Get next buffer from todevice queue and make &quot;visible&quot; to ISR.</td>
</tr>
<tr>
<td></td>
<td>2) Call Dxx_issue()</td>
<td>2) If first &quot;issue,&quot; enable interrupts</td>
</tr>
<tr>
<td>SIO_reclaim(outstream,bufp,parg,timeout)</td>
<td>1) Call Dxx_reclaim()</td>
<td>2) Get empty bufp from fromdevice queue</td>
</tr>
<tr>
<td></td>
<td>2) Get empty bufp from fromdevice queue</td>
<td>Pend on semaphore until an empty buffer is available on fromdevice queue</td>
</tr>
</tbody>
</table>

**Figure 7-11. Retrieving Buffers from a Stream**

<table>
<thead>
<tr>
<th>Application</th>
<th>SIO_module</th>
<th>Dxx_module</th>
</tr>
</thead>
<tbody>
<tr>
<td>SIO_issue(outstream,bufp,nbytes,arg)</td>
<td>1) Put empty bufp on todevice queue</td>
<td>1) Get next buffer from todevice queue and make &quot;visible&quot; to ISR,</td>
</tr>
<tr>
<td></td>
<td>2) Call Dxx_issue()</td>
<td>2) If first &quot;issue,&quot; enable interrupts</td>
</tr>
<tr>
<td>SIO_reclaim(outstream,bufp,parg,timeout)</td>
<td>1) Call Dxx_reclaim()</td>
<td>2) Get full bufp from fromdevice queue</td>
</tr>
<tr>
<td></td>
<td>2) Get full bufp from fromdevice queue</td>
<td>Pend on semaphore until a full buffer is available on fromdevice queue</td>
</tr>
</tbody>
</table>
Figure 7-29 is a template for Dxx_issue for a typical terminating device.

**Example 7-29. Template for Dxx_issue for a Typical Terminating Device**

```c
/*
 * ======== Dxx_issue ========
 */
Int Dxx_issue(DEV_Handle device)
{
    Dxx_Handle objptr = (Dxx_Handle) device->object;
    if ( device is not operating in correct mode )
    {
        'start the device for correct mode'
    }
    return (SYS_OK);
}
```

A call to Dxx_issue starts the device for the appropriate mode, either DEV_INPUT or DEV_OUTPUT. Once the device is known to be started, Dxx_issue simply returns. The actual data handling is performed by an HWI.

Figure 7-30 is a template for Dxx_reclaim for a typical terminating device.

**Example 7-30. Template for Dxx_reclaim for a Typical Terminating Device**

```c
/*
 * ======== Dxx_reclaim ========
 */
Int Dxx_reclaim(DEV_Handle device)
{
    Dxx_Handle objptr = (Dxx_Handle) device->object;
    if (SEM_pend(objptr->sync, device->timeout))
    {
        return (SYS_OK);
    }
    else { /* SEM_pend() timed out */
        return (SYS_ETIMEOUT);
    }
}
```

A call to Dxx_reclaim waits for the HWI to place a frame on the device->fromdevice queue, then returns.

Dxx_reclaim calls SEM_pend with the timeout value specified at the time the stream is created (either by the Configuration Tool or with SIO_create) with this value. If the timeout expires before a buffer becomes available, Dxx_reclaim returns SYS_ETIMEOUT. In this situation, SIO_reclaim does not attempt to get anything from the device->fromdevice queue. SIO_reclaim returns SYS_ETIMEOUT, and does not return a buffer.
7.14 Closing Devices

A device is closed by calling SIO_delete, which in turn calls Dxx_idle and Dxx_close. Dxx_close closes the device after Dxx_idle returns the device to its initial state, which is the state of the device immediately after it was opened. This is shown in Example 7-31.

Example 7-31. Closing a Device

```c
/* ======== Dxx_idle ======== */
Int Dxx_idle(DEV_Handle device, Bool flush)
{
    Dxx_Handle objptr = (Dxx_Handle) device->object;
    Uns post_count;

    /* The only time we will wait for all pending data
     * is when the device is in output mode, and flush
     * was not requested.
     */
    if ((device->mode == DEV_OUTPUT) && !flush)
    {
        /* first, make sure device is started */
        if (device is not started &&
            'device has received data') {
            'start the device'
        }

        /* wait for all output buffers to be consumed by the
         * output HWI. We need to maintain a count of how many
         * buffers are returned so we can set the semaphore later.
         */
        post_count = 0;
        while (!QUE_empty(device->todevice)) {
            SEM_pend(objptr->sync, SYS_FOREVER);
            post_count++;
        }

        if ('there is a buffer currently in use by the HWI') {
            SEM_pend(objptr->sync, SYS_FOREVER);
            post_count++;
        }

        'stop the device'
    }

    return device
```

Closing Devices
Example 7.31. Closing a Device (continued)

The arguments to Dxx_idle are:

```c
DEV_Handle device;    /* driver handle */
Bool        flush;     /* flush indicator */
```

The device parameter is, as usual, a pointer to a DEV_Obj for this instance of the device. flush is a boolean parameter that indicates what to do with any pending data while returning the device to its initial state.

For a device in input mode, all pending data is always thrown away, since there is no way to force a task to retrieve data from a device. Therefore, the flush parameter has no effect on a device opened for input.

For a device opened for output, however, the flush parameter is significant. If flush is TRUE, any pending data is thrown away. If flush is FALSE, the Dxx_idle function does not return until all pending data has been rendered.
7.15 Device Control

Dxx_ctrl is called by SIO_ctrl to perform a control operation on a device. A typical use of Dxx_ctrl is to change the contents of a device control register or the sampling rate for an A/D or D/A device. Dxx_ctrl is called as follows:

\[
\text{status} = \text{Dxx_ctrl(DEV\_Handle device, Uns cmd, Arg arg)};
\]

- cmd is a device-specific command.
- arg provides an optional command argument.

Dxx_ctrl returns SYS_OK if the control operation was successful; otherwise, Dxx_ctrl returns an error code.

7.16 Device Ready

Dxx_ready is called by SIO_select to determine if a device is ready for I/O. Dxx_ready returns TRUE if the device is ready and FALSE if the device is not. The device is ready if the next call to retrieve a buffer from the device will not block. This usually means that there is at least one available frame on the queue device->fromdevice when Dxx_ready returns as shown in Example 7-32. Refer to section 7.6, Selecting Among Multiple Streams, page 7-24, for more information on SIO_select.

Example 7-32. Making a Device Ready

```c
Bool Dxx_ready(DEV\_Handle dev, SEM\_Handle sem)
{
    Dxx\_Handle objptr = (Dxx\_Handle)device->object;
    /* register the ready semaphore */
    objptr->ready = sem;

    if ((device->mode == DEV\_INPUT) &&
        (device->model == DEV\_STANDARD) &&
        'device is not started')
    {
        'start the device'
    }

    /* return TRUE if device is ready */
    return ( 'TRUE if device->fromdevice has a frame or
device won’t block');
}
```

If the mode is DEV\_INPUT, the streaming model is DEV\_STANDARD. If the device has not been started already, the device is started. This is necessary, since in the DEV\_STANDARD streaming model, SIO_select can be called by the application before the first call to SIO\_get.
The device’s ready semaphore handle is set to the semaphore handle passed in by SIO_select. To better understand Dxx_ready, consider the following details of SIO_select.

SIO_select can be summarized in pseudocode as shown in Example 7-33.

Example 7-33. SIO_Select Pseudocode

```c
/*  """ SIO_select """  */
Uns SIO_select(streamtab, n, timeout)
    SIO_Handle streamtab[];    /* array of streams */
    Int n;                    /* number of streams */
    Uns timeout;             /* passed to SEM_pend() */
{
    Int i;
    Uns mask = 1;              /* used to build ready mask */
    Uns ready = 0;            /* bit mask of ready streams */
    SEM_Handle sem;           /* local semaphore */
    SIO_Handle *stream;       /* pointer into streamtab[] */
    
    /* For efficiency, the "real" SIO_select() doesn’t call 
    * SEM_create() but instead initializes a SEM_Obj on the 
    * current stack. 
    */
    sem = SEM_create(0, NULL);

    stream = streamtab;
    for (i = n; i > 0; i--, stream++) {
        /* call each device ready function with ‘sem’ */
        if ( `Dxx_ready(device, sem)` )
            ready = 1;
    }
    if (!ready) {
        /* wait until at least one device is ready */
        SEM_pend(sem, timeout);
    }
    ready = 0;

    stream = streamtab;
    for (i = n; i > 0; i--, stream++) {
        /* Call each device ready function with NULL. 
        * When this loop is done, ready will have a bit set 
        * for each ready device. */
        if ( `Dxx_ready(device, NULL)` )
            ready |= mask;
        mask = mask << 1;
    }

    return (ready);
}
```
SIO_select makes two calls to Dxx_ready for each Dxx device. The first call is used to register sem with the device, and the second call (with sem = NULL) is used to un-register sem.

Each Dxx_ready function holds on to sem in its device-specific object (for example, objptr->ready = sem). When an I/O operation completes (that is, a buffer has been filled or emptied), and objptr->ready is not NULL, SEM_post is called to post objptr->ready.

If at least one device is ready, or if SIO_select was called with timeout equal to 0, SIO_select does not block; otherwise, SIO_select pends on the ready semaphore until at least one device is ready, or until the time-out has expired.

Consider the case where a device becomes ready before a time-out occurs. The ready semaphore is posted by whichever device becomes ready first. SIO_select then calls Dxx_ready again for each device, this time with sem = NULL. This has two effects. First, any additional Dxx device that becomes ready will not post the ready semaphore. This prevents devices from posting to a semaphore that no longer exists, since the ready semaphore is maintained in the local memory of SIO_select. Second, by polling each device a second time, SIO_select can determine which devices have become ready since the first call to Dxx_ready, and set the corresponding bits for those devices in the ready mask.
7.17 Types of Devices

There are two main types of devices: terminating devices and stackable devices. Each exports the same device functions, but they implement them slightly differently. A terminating device is any device that is a data source or sink. A stackable device is any device that does not source or sink data, but uses the DEV functions to send (or receive) data to or from another device. Refer to Figure 7-12 to see how the stacking and terminating devices fit into a stream.

Figure 7-12. Stacking and Terminating Devices

Within the broad category of stackable devices, there are two distinct types. These are referred to as in-place stacking devices and copying stacking devices. The in-place stacking device performs in-place manipulations on data in buffers. The copying stacking device moves the data to another buffer while processing the data. Copying is necessary for devices that produce more data than they receive (for example, an unpacking device or an audio decompression driver), or because they require access to the whole buffer to generate output samples and cannot overwrite their input data (for example, an FFT driver). These types of stacking devices require different implementation, since the copying device might have to supply its own buffers.

Figure 7-13 shows the buffer flow of a typical terminating device. The interaction with DSP/BIOS is relatively simple. Its main complexities exist in the code to control and stream data to and from the physical device.
Figure 7-13. Buffer Flow in a Terminating Device

Figure 7-14 shows the buffer flow of an in-place stacking driver. All data processing is done in a single buffer. This is a relatively simple device, but it is not as general-purpose as the copying stacking driver.

Figure 7-14. In-Place Stacking Driver
Figure 7-15 shows the buffer flow of a copying stacking driver. Notice that the buffers that come down from the task side of the stream never actually move to the device side of the stream. The two buffer pools remain independent. This is important, since in a copying stacking device, the task-side buffers can be a different size than the device-side buffers. Also, care is taken to preserve the order of the buffers coming into the device, so the SIO_ISSUERECLAIM streaming model can be supported.

Figure 7-15. Copying Stacking Driver Flow
